

COMMENTS ON  $A_2$  PRODUCTION

C. MICHAEL and P. V. RUUSKANEN\*

CERN, Geneva, Switzerland

Received 2 April 1971

We discuss the analysis of high energy  $A_2$  production data, including comparisons with  $\omega$  and  $f_0$  production and possible  $f_0 - A_2$  interference effects.

The  $A_2$  resonance region mass spectrum and its decay characteristics have been studied in many experiments. However, the production mechanisms have received much less attention. Now that the  $A_2$  is seen [1] at higher energies as a single state with a width of about 100 MeV, we feel that it is meaningful to discuss the production process. The  $A_2$  state produced at higher energies we shall treat as the normal  $A_2$ , to be identified with the SU(3) partner of the  $f_0$ ,  $f_0'$  and  $K^*(1420)$  and as the exchange degenerate partner of the  $\rho$  and  $g$ . Any narrow destructively interfering dip or splitting seen at lower energy [2] may then be treated † as a small perturbation on the dominant normal  $A_2$  production. We shall summarize some theoretical approaches to high energy production of  $A_2$  in  $\pi N \rightarrow A_2 N$ . Some specific predictions from absorbed Regge cut models and from comparisons with  $\pi N \rightarrow A_2 \Delta$ ;  $\pi N \rightarrow f_0 N$ ;  $\pi N \rightarrow \omega N$ , etc., will be presented. We discuss finally the possibility of observing  $f_0 - A_2$  interferences in the reactions  $\pi N \rightarrow KKN$  and  $\pi N \rightarrow K\bar{K}\Delta$  at high energy.

*Parity exchanged.* General arguments [3] give the following decomposition, valid to  $O(1/s)$ , into unnatural (U) and natural (N) parity exchange in

\* On leave from Department of Theoretical Physics University of Helsinki, Helsinki, Finland.

† The nearly maximum destructive interference claimed [2] in 3 and 7 GeV/c  $A_2^-$  production and 3 GeV/c  $A_2^0$  production requires  $A_2$  (normal state) and  $\tilde{A}_2$  (anomaly) amplitudes to be comparable in strength, coherent in spin structure and precisely related in phase. If the  $\tilde{A}_2$  is produced by lower lying Regge trajectories, the splitting will go away with increasing energy but it would require additional strong phase or coherence changes to produce a large splitting at 3 and 7 GeV/c and none at 17 and 20 GeV/c. However, it would be relatively easy to arrange a phase or coherence difference between  $A_2^+$  and  $A_2^-$  production at 7 GeV/c to explain the lack of splitting for  $A_2^+$ .

terms of the  $A_2$  density matrix elements

$$\rho_1^N = \rho_{11} + \rho_{1-1}, \quad \rho_2^N = \rho_{22} - \rho_{2-2}, \quad \rho_0^U = \rho_{00},$$

$$\rho_1^U = \rho_{11} - \rho_{1-1}, \quad \rho_2^U = \rho_{22} + \rho_{2-2}$$

where  $\rho_{ij}$  is measured in any frame with  $y$  axis normal to the production plane [such as the  $s$  channel helicity frame (SHF) or the Gottfried-Jackson frame (THF)]. Experimentally, for the  $3\pi$  mode of  $A_2$  decay, the density matrix elements can only be measured when a complete spin-parity analysis is performed to select  $J^P = 2^+$  states from the background. For the  $K\bar{K}$  mode, the background to the  $A_2$  signal is much smaller. Data suggest [4]  $\rho_{11} \sim \rho_{1-1} \sim 0.5$  with all other elements small to a first approximation in the THF. This indicates a dominance of natural parity exchanges.

*Quark model.* In the quark model the  $A_2$  is an  $l = 1$   $q\bar{q}$  state so that excitation from a  $\pi$  meson necessitates adding angular momentum to the  $q\bar{q}$  system. Arguments [5] have been given that this angular momentum to be added will be perpendicular to the production plane in the THF. Then the resulting  $qq$  state has only helicity 0 or 1 coming from a quark spin flip in the THF and so  $\rho_{2i} = 0$  for all  $i$ . Data [4] for  $\pi^- p \rightarrow A_2^- p$  confirm this suggestion.

*Isospin.* We shall use  $f_0$  and  $\rho$  to denote isospin 0 and 1 exchanges for convenience. Then for the amplitudes,

$$\pi^- p \rightarrow A_2^- p = f_0 + \rho$$

$$\pi^+ p \rightarrow A_2^+ p = f_0 - \rho$$

$$\pi^- p \rightarrow A_2^0 n = \sqrt{2} \rho.$$

Experimental cross-section data show [6]  $\sigma^- \sim \sigma^+ \sim 2 \sigma^0$  so that  $I_t = 0$  exchanges must be dominant.

$\rho, f_0$  Regge poles. To proceed further we shall

discuss the natural parity exchanges  $\rho$  and  $f_0$  since they seem to dominate in the data. For the THF amplitudes, only  $\lambda_{A_2} = 1$  contributes if the quark model argument is valid. Thus  $\rho_{11} = \rho_{1-1} = 0.5$  and all other elements are zero. To discuss the structure of the helicity amplitudes and eventual absorption corrections we shall, however, discuss the SHF amplitudes.

Then for exchange of a natural parity Regge pole  $X$  in SHF amplitude  $F_{if}^{\lambda A_2}(n)$ , where  $i$  and  $f$  are initial and final nuclear helicities and  $n$  is the over-all helicity flip, we will have  $F^0 = 0$  and

$$F_{++}^1(1) = F_{--}^1(1) = \sqrt{\frac{t_0-t}{4m^2}} \gamma_{XNN}^{++} \gamma_{X\pi A_2}^1 R(X)$$

$$F_{++}^2(2) = F_{--}^2(2) = \left(\frac{t_0-t}{4m^2}\right) \gamma_{XNN}^{++} \gamma_{X\pi A_2}^2 R(X)$$

$$F_{+-}^1(2) = F_{-+}^1(0) = \left(\frac{t_0-t}{4m^2}\right) \gamma_{XNN}^{+-} \gamma_{X\pi A_2}^1 R(X)$$

$$F_{+-}^2(3) = F_{-+}^2(1) = \left(\frac{t_0-t}{4m^2}\right)^{3/2} \gamma_{XNN}^{+-} \gamma_{X\pi A_2}^2 R(X).$$

The  $\rho$  and  $f_0$  couplings to  $\pi A_2$  can be obtained from duality considerations in the three reactions  $\pi^+\pi^+ \rightarrow \pi^+\pi^+$ ,  $\pi^+\pi^+ \rightarrow \pi^+A_2^+$  and  $\pi^+\pi^+ \rightarrow A_2^+A_2^+$ . The natural parity exchanges in each case are  $\rho$  and  $f_0$  and these must cancel in the imaginary part since doubly charged mesons are not observed. Then the  $\pi^+A_2^+$  Regge couplings of  $\rho$  and  $f_0$  must be equal, both for  $\lambda(A_2) = 1$  and 2 separately:  $\gamma_{\rho\pi A_2}^\lambda = \gamma_{f_0\pi A_2}^\lambda$ . The  $\lambda = 1$  and 2 vertices may be related from the quark model argument that they correspond to pure  $\lambda = 1$  after transformation to the THF.

The  $\rho$  and  $f_0$  SHF couplings to NN are well known [7] and  $\rho$  dominates the spin flip while  $f_0$  dominates the non-flip:

$$\gamma_{f_0 NN}^{++} \sim 5 \gamma_{NN}^{++}, \quad \gamma_{f_0 NN}^{+-} \sim -0.1 \gamma_{\rho NN}^{+-}$$

$$\gamma_{\rho NN}^{+-} \sim -5 \gamma_{\rho NN}^{++}$$

A further difference arises from the signature factors  $R(f_0) = (1 + \exp(-i\pi\alpha))R$  and  $R(\rho) = (-1 + \exp(-i\pi\alpha))R$ .

Then the dominant contribution will be the  $f_0$  contribution to  $F(1)$  since it has a large residue and a small power of  $(t-t_0)$ . The next most important contributions come from the  $\rho$  in  $F(1)$ ,  $F(2)$  and  $F(0)$ . The  $\rho$  contribution to the cross-section should then be much smaller than the  $f_0$  contribution although possible contributions from cuts in  $F_{+-}^1(0)$  make this somewhat model dependent. With  $\rho$  and  $f_0$  out of phase by  $90^\circ$ ,

the cross-section data quoted previously give  $|f|^2 \sim 3|\rho|^2$  for the averaged contributions. This is quite consistent with our discussion. Also all pole amplitudes vanish in the forward direction in agreement with  $d\sigma/dt$  data [4, 8] that show a forward turn-over.

*Regge cut modifications.* Since the Pomeron is assumed to conserve  $s$  channel helicity, the characteristics of absorption corrections are simpler to discuss in the SHF. Thus for  $\rho$  and  $f_0$ , no contributions will arise to  $\rho_{00}$  even after absorption. The major change will be to the amplitude  $F_{+-}^1(0)$ , which has a factor  $(t-t_0)$  for a factorizing Regge pole, whereas the cut correction is non-zero at  $t=0$ . This cut contribution will have  $I_t = 1$ . We then predict that at the forward direction the cross-section for  $A_2^0$  production is twice as large as for  $A_2^+$  production. Thus the forward dip in  $A_2^0$  production should be less sharp than in  $A_2^+$  production.

The effect of such a  $\rho$  cut in  $F_{+-}^1(0)$  on the density matrix elements should be larger for  $A_2^0$  production than for  $A_2^+$  production since the  $I_t = 1$  relative contributions are different. When transformed to the THF, the cut will also enter the amplitudes with  $\lambda_{A_2} = 0$  and 2. A measure of the cut contribution is then  $\rho_{00}$  in the THF and this is  $\leq 0.1$  for present  $A_2^+$  production data. The contribution to  $\rho_{20}$  and  $\rho_{22}$  should be smaller than that to  $\rho_{00}$  while  $\rho_{10}$  and  $\rho_{21}$  receive contributions from cut-pole interference and could be more significantly modified.

At  $t = -0.6 \text{ GeV}^2$  the  $\rho$  Regge pole amplitudes vanish while those for  $f_0$  do not. Thus no dip is expected in  $\pi^\pm p \rightarrow A_2^\pm p$  at this value of momentum transfer while for  $\pi^\pm p \rightarrow A_2^0 n$  the pole amplitudes are zero so that a dip is expected in a weak cut model. For the strong cut or Michigan model, however, zeros are anticipated [9] in single flip amplitudes at  $t = -0.6 \text{ GeV}^2$  irrespective of the pole signature. Since we have argued that  $\pi_p^\pm \rightarrow A_2^\pm p$  is dominated by single flip, this would lead to such a dip at  $-0.6 \text{ GeV}^2$  although present data [8] give no indication of any such structure. For  $\pi^- p \rightarrow A_2^0 n$ , a mixture of amplitudes is expected and the Michigan model would suggest the absence of a dip. For this reaction  $\rho_2^N d\sigma/dt$  could be useful for dip hunting since the over-all non-flip amplitude does not contribute.

*Unnatural parity exchanges.* The exchange contributions of  $\eta$  and B mesons seem to be small experimentally for  $\pi^\pm p \rightarrow A_2^\pm p$ . The  $\eta NN$  coupling is known to be small [7]. Furthermore,  $\eta$  has a low lying trajectory, and so it should be negligible at higher energies. The B contribution relative to  $\rho$  can be argued to be similar for  $\omega$

production and for  $A_2^0$  production from a duality discussion of  $\pi^+\pi^+ \rightarrow \rho^+\rho^+$  and  $\pi^+\pi^+ \rightarrow B+B^+$ . Then unnatural parity contributions  $\rho_0^U$  and  $\rho_1^U$  should be of the same size for  $\omega$  and  $A_2^0$  production while  $\sim 25\%$  smaller for  $A_2^\pm$  production which is dominated by  $I_t = 0$  exchange. This would also explain the claimed [6] difference in the energy dependence between the neutral and charged  $A_2$  production cross-sections, the latter [6] being in good agreement with  $\rho$  and  $f_0$  exchanges.

Another source of unnatural parity exchange contributions arises from cut modifications to  $\rho$  and  $f_0$  as discussed above. We have argued that these will not contribute to  $\rho_{00}$  in the SHF. The energy dependence of such effects should be different from those due to lower lying  $\eta$  and  $B$  contributions.

*Comparison with other reactions.* For natural parity exchanges one expects  $\pi N \rightarrow A_2 \Delta$  to show similar features to  $\pi^- p \rightarrow A_2^0 n$  since the  $N\Delta\rho$  vertex is flip dominated like the  $N\bar{N}\rho$  vertex. Another reaction with similar exchanges is  $\pi N \rightarrow \omega N$  (and  $\pi N \rightarrow \omega \Delta$ ) where  $\rho$  and  $B$  are allowed. As discussed previously, a comparison of unnatural parity exchange contributions in  $A_2^0$  production with the contributions ( $\rho_{00} \sim 0.3$  at high energies) found in  $\omega$  production is of interest. Features of  $\rho_1^N d\sigma/dt$  should be the same for  $\omega$  production as for  $A_2^0$  production, however. This quantity for production seems [10] to show a dip at  $t \sim -0.6$ . Similarly  $d\sigma/dt$  for  $\pi N \rightarrow A_2 \Delta$  at 3.7 GeV/c [11] shows such structure. We would thus expect such a dip for  $\pi^- p \rightarrow A_2^0 n$ .

Another source of comparison is the reaction  $\pi N \rightarrow f_0 N$ . Here  $\pi$  exchange dominates but  $\rho_1^N$  and  $\rho_2^N$  select out  $A_2$  exchange. Since the  $\rho\pi A_2$  and  $f_0\pi A_2$  couplings are equal from EXD arguments we predict that, for Regge pole exchange,

$$\tan^2(\frac{1}{2}\pi\alpha) \rho_1^N \frac{d\sigma}{dt}(\pi^- p \rightarrow f_0 n) = \rho_1^N \frac{d\sigma}{dt}(\pi^- p \rightarrow A_2^0).$$

The modification of  $F(0)$  by cuts will perturb this relation somewhat. A final amusing consequence is that, in the  $\bar{K}K$  decay mode, it is possible to observe interference between  $f_0$  and  $A_2$ . The Regge pole exchanges give a  $90^\circ$  phase difference in production due to the  $A_2$  and  $\rho$  signature factors. Then at a mass between the  $f_0$  and  $A_2$  resonance peaks where the Breit-Wigner phases are about  $135^\circ$  for  $f_0$  and  $45^\circ$  for  $A_2$ , one may have substantial interference. From duality diagram arguments the interference will be destructive for  $\pi^+ n \rightarrow (\bar{K}K)^0 p$  and for  $\pi^+ p \rightarrow (\bar{K}K)^0 \Delta^{++}$  and constructive for  $\pi^- p \rightarrow (\bar{K}K)^0 n$ . Using  $\rho_1^N d\sigma/dm^2$  to select natural parity exchange, since EXD gives equal  $f_0$  and  $A_2$  couplings to  $\bar{K}K$  and also equal  $A_2$  and  $\rho$  production amplitudes (apart from signature factors), one will have

equal strength amplitudes and full coherence in the  $A_2 - f_0$  interference. Note that  $\rho_{00} d\sigma/dm^2$  should, however, separate out almost pure  $f_0$  production proceeding by  $\pi$  exchange.

*Conclusion.* Present data on the production of the normal  $A_2$  can be understood naturally with  $\rho$  and  $f_0$  exchange where  $f_0$  exchange is dominant. We have discussed the helicity amplitude structure of the exchange contributions and presented expectations for density matrix elements and differential cross-section structure. Comparisons with other reactions were presented and  $f_0 - A_2$  interference was discussed.

The most useful data to further such analyses would be measurements of  $d\sigma/dt$  and density matrix elements as functions of  $t$  including the important regions  $t \sim t_{\min}$  and  $t \sim -0.6$  GeV<sup>2</sup>. Measurements at widely separated energies (say 10 and 20 GeV/c) for  $A_2^\pm$  and  $A_2^0$  production with accurate relative normalization will be most valuable.

We are pleased to thank Dr. J. Tran Thanh Van, Dr. P. Weilhammer and Dr. K. Lassila for useful and interesting discussions.
