# Jini™ Technology Helper Utilities And Services Specification

The Jini™ technology infrastructure is a distributed system based on Java™ technology and is designed around the goals of simplicity, flexibility, and federation. Jini technology helper utility and service classes are intended to aid in the process of building clients and services that will participate in the application environment for Jini technology. This document describes the functionality and operational requirements of the current set of classes that satisfy the definition of a Jini technology helper utility or a Jini technology helper service.

# About This Document

## 0.1 Status

**T**his document is the 1.1Alpha version of the Jini™ Technology Helper Utilities And Services Specification. The primary purpose of publishing at this time is to gather comments from a wider audience on the design and usefulness of these utilities. As a welcome side effect, we will also gather data on the utility of this document itself—we encourage editorial as well as technical comment.

This specification is only one of many Jini specifications that together would describe the functionality of a 1.1 release of Jini technology. Please note that this specification may change in any way, including its title, organization, or content, without notice. Any part of this specification may at a later date be deleted, subsumed by an existing Jini specification, or become a separate Jini specification. As with any draft, all details are subject to change without notice.

## 0.2 Annotations

---

**Note:** In this document you will see several paragraphs in this style. These are areas where we specifically invite comment. Consider them as “notes to reviewers.”

---

## 0.3 Comments

Please direct comments to [jini-comments@sun.com](mailto:jini-comments@sun.com)

---

# Introduction

## 1.1 Overview

When developing clients and services that will participate in the application environment for Jini™ technology, there are a number of behaviors that the developer may find desirable to incorporate in the client or service. Some of these behaviors may satisfy requirements described in the specifications of various Jini technology components; some behaviors may simply represent design practices that are desirable and should be encouraged. Examples of the sort of behavior that is required or desirable include the following:

- ◆ It is a requirement of the Jini discovery protocol that a service must continue to listen for and act on announcements from lookup services in which the service has registered interest.
- ◆ It is a requirement of the Jini discovery protocol that, until successful, a service must continue to attempt to join the specific lookup services with which it has been configured to join.
- ◆ Under many conditions, a Jini technology-enabled client or service will wish to regularly renew leases that it holds. For example, when a Jini technology-enabled service registers with a Jini lookup service, the service is requesting residency in the lookup service. Residency in a lookup service is a leased resource. Thus, when the requested residency is granted, the lookup service also imposes a lease on that residency. Typically, such a registered service will wish to extend the lease on its residency beyond the original expiration time; resulting in a need to renew the lease on a regular basis.
- ◆ Many Jini technology-enabled services will need to maintain a dormant (inactive) state; becoming active only when needed.

- ◆ Many Jini technology-enabled clients and services will need to have a mechanism for finding and managing Jini technology-enabled services.
- ◆ Many Jini technology-enabled clients and services will find it desirable to employ a separate service that will handle events, in some useful way, on behalf of the participant.

In order to help simplify the process of developing clients and services for the application environment for Jini technology, a set of reusable components, which encapsulate behaviors such as those outlined above, will be specified in this document. These components will take the form of *helper* utilities and services. Employing these utilities and services to build such desirable behavior into a Jini technology-enabled client or service can help to avoid poor design and implementation decisions, greatly simplifying the development process.

Note that when this document uses either the word “must” or the word “will” to describe a behavior of one of the helper utility or service classes, that behavior is considered a requirement. When this document describes a behavior using the word “should” — or otherwise indicates that the behavior is desirable — the behavior is highly recommended but not required.

## 1.2 Terminology

This section defines terms and discusses concepts that may be referenced throughout the chapters of this document. While the terms and concepts appearing in this section are general in nature and may apply to multiple components specified in this document, each chapter may define additional terms and concepts to further facilitate the understanding of a particular component’s specification. Each chapter may also present supplemental information about some of the terms defined in this section and their relationship with the component being specified.

Because this specification makes use of a number of terms defined in the *Jini™ Technology Glossary*, reviewing that document is recommended. A number of the terms defined in the glossary are also defined in this section to provide easy reference, and because those terms are used extensively in this document. Additionally, this section augments the definitions of some of the terms from the glossary with details relevant to this specification.

In addition to the glossary, the Jini specifications present detailed definitions of a number of terms and concepts appearing both in this section and throughout this document. When appropriate, the relevant Jini specification will be referenced.

### 1.2.1 Terms Related to Discovery and Join

The *Jini™ Discovery and Join Specification* defines a *discovering entity* as one or more cooperating software objects written in the Java™ programming language (*Java software objects*), executing on the same host, that are in the process of obtaining references to Jini lookup services. That specification also defines a *joining entity* as one or more cooperating Java software objects, on the same host, that have received a reference to a lookup service and are in the process of obtaining services from, and possibly exporting services to, a federation of lookup services referred to as a *djinn*. The lookup services comprising a djinn may be organized into one or more sets known as *groups*. Multiple groups may or may not be disjoint. Each group of lookup services is identified by a logical name represented by a `String` object.

The *Jini™ Discovery and Join Specification* defines two protocols used in the discovery process: the *multicast discovery protocol* and the *unicast discovery protocol*.

When a discovering entity employs the multicast discovery protocol to discover lookup services that are members of one or more groups belonging to a set of groups, that discovery process is referred to as *group discovery*.

The utility class `net.jini.core.discovery.LookupLocator` is defined in the *Jini™ Discovery Utilities Specification*. Any instance of that class is referred to as a *locator*. When a discovering entity employs the unicast discovery protocol to discover specific lookup services, each corresponding to an element in a set of locators, that discovery process is referred to as *locator discovery*.

### 1.2.2 Jini Technology-Enabled Clients and Services

For the purposes of this document, a Jini technology-enabled client (*Jini client*) is defined as a discovering entity that can retrieve a service (or a remote reference to a service) registered with a discovered lookup service; and invoke the methods of the service so as to meet the entity's requirements. An entity that acts only as a client never registers with (requests residency in) a lookup service.

A Jini technology-enabled service (*Jini service*) is defined as both a discovering and a joining entity containing methods which may be of use to some other Jini client or service, and which registers with discovered lookup services to provide access to those methods. Note that a Jini service can also act as a Jini client.

The term *client-like entity* may be used, in general, when referring to Jini clients and Jini services that act as clients.

Note that when the term *entity* is used, that term may be referring to a discovering entity, a joining entity, a client-like entity, a service, or some combination of

these types of entities. Whenever that general term is used, it should be clear from the context what type of entity is being discussed.

### 1.2.3 Helper Service

A Jini technology *helper service* is defined in this document as an interface or set of interfaces, with an associated implementation, that encapsulates behavior that is either required or highly desirable in service entities that adhere to the Jini technology programming model (or simply, the *Jini programming model*). A helper service is a Jini service that can be registered with any number of lookup services, and whose methods can execute on remote hosts.

A helper service should be of use to more than one type of entity participating in the application environment for Jini technology (*Jini application environment*), and should provide a significant reduction in development complexity for developers of such entities.

### 1.2.4 Helper Utility

This document distinguishes between a helper *utility* and a helper *service*. Helper utilities are programming components that can be used during the construction of Jini services and/or clients. Helper utilities are *not* remote and do not register with a lookup service. Helper utilities are instantiated locally by entities wishing to employ them.

### 1.2.5 Managed Sets

When performing discovery duties, entities will often maintain references to discovered lookup services in a set referred to as the *managed set of lookup services*. The entity may also maintain two other notable sets: the *managed set of groups* and the *managed set of locators*.

Each element of the managed set of groups is a name of a group whose members are lookup services that the entity wishes to be discovered. These interfaces represent this set as a `String` array.

Each element of the managed set of locators corresponds to a specific lookup service that the entity wishes to be discovered. Typically, this set is represented as an array of `net.jini.core.discovery.LookupLocator` objects.

Note that when the general term *managed set* is used, it should be clear from the context whether groups, locators, or lookup services are being discussed.

### 1.2.6 Unavailable Lookup Services

While interacting (or attempting to interact) with a lookup service, an entity may encounter an exception or error condition. Depending on the nature of the exception or error encountered, the entity may interpret the situation to mean that the lookup service is simply no longer available; that is, the lookup service is *unavailable*.

For most entities, the unavailability of a particular lookup service should not prevent the entity from continuing its processing. Although there are a number of exception and error conditions that in other situations might be considered unrecoverable (or fatal) to an entity, when the condition indicates an unavailable lookup service, the entity should catch and handle the exception or error and continue processing.

The set of exceptions and errors that are non-fatal to an entity when interacting with a lookup service is dependent on the nature of the entity. Thus, each entity must specify its own set of non-fatal exceptions and errors for identifying unavailable lookup services.

Although this document cannot specify a single, definitive set of non-fatal exceptions and errors that meets the needs of all entities, a set that may meet the needs of *most* entities is presented here:

- ◆ `java.lang.Exception`
- ◆ `java.lang.LinkageError`
- ◆ `java.lang.OutOfMemoryError`
- ◆ `java.lang.StackOverflowError`

Thus, when any of the conditions in the list above (or the conditions defined by the entity itself) occur while the entity is interacting with a lookup service, the lookup service should be considered unavailable. Whenever an entity encounters an unavailable lookup service, the entity should catch and handle the condition; usually by requesting that the unavailable lookup service be discarded (see below). For all other exceptions and errors considered fatal, the entity should not attempt to recover.

### 1.2.7 Discarding a Lookup Service

When an already-discovered lookup service is removed from the managed set of lookup services, it is said to be *discarded*. The process of discarding a lookup service is initiated, either directly or indirectly, by the discovering entity.

When the entity encounters an unavailable lookup service, the entity typically will request that the unavailable lookup service be discarded. Additionally, whenever the entity requests the removal of an element from the managed set of groups or locators, one or more of the lookup services associated with the removed elements may be discarded. For this case, whether or not the discard process is executed is dependent on the state of the managed sets after the removal request has been processed.

Whenever a lookup service is discarded, a notification event referencing the discarded lookup service will be sent to all of the entity's discovery listeners. This event is referred to as a *discard event*.

If a lookup service is discarded because it was found to be unavailable, that lookup service will be made eligible for re-discovery. In this case, the process of discarding a lookup service can be viewed as a mechanism for the removal of stale entries in the managed set of lookup services. The discarded lookup service is effectively "marked" for re-discovery, removing the need for operations such as lease renewal attempts on a lookup service that is currently unavailable. Upon re-discovery of the discarded lookup service, the implementation object will process the re-discovered lookup service as if it were discovered for the first time.

If a lookup service is discarded because the group(s) or locator with which it is associated have been removed from their respective managed set, the lookup service is no longer eligible for discovery until those group(s) or that locator are again added to the appropriate managed set.

## Remote Objects, Stubs and Proxies

The *Jini™ Technology Glossary* states that a *remote object* is an object whose methods can be invoked from a Java virtual machine (JVM), potentially on a different host. Furthermore, the glossary states that such an object is described by one or more *remote interfaces*.

When invoking methods remotely through Java Remote Method Invocation (RMI), it is useful to think of the invocation as consisting of two components: a client component and a server component. When the client component initiates a remote method call, the server component carries out the execution of the remote method, and RMI facilitates the necessary communication between the two parties. Note that when discussing concepts related to RMI, the term *server* (or *remote server*) is sometimes used in place of the term *remote object*.

In order to initiate the invocation of a remote method, the client must have access to an object referred to as the *stub* of the remote object. The stub is an object local to the client that acts as the "representative" of the remote object. The stub implements the same set of remote interfaces that the remote object implements. From the point of view of the client, the stub *is* the remote object. When

the client invokes a method on the local stub, communication with the remote object occurs, resulting in the execution of the corresponding method in the remote object's JVM.

The term *proxy* is used extensively throughout this document. With respect to remote objects in general, and entities operating within a Jini application environment in particular, a proxy is simply an intermediary object through which one entity (the client) may request the invocation of the methods provided by another entity (the remote object or the service).

Proxies can take a number of different forms. Some proxies take the form of what is often referred to as a *smart proxy*. This type of proxy typically consists of a set of local methods and a set of one or more remote object references (stubs). Clients invoke one or more of the local methods to access the methods of the remote objects referenced in the proxy.

Another form that a proxy can take is that of the stub of a remote object. That is, all stubs are simply proxies to their corresponding remote objects. Except for the local methods `equals` and `hashCode`, this type of proxy consists of remote methods only.

Some proxies are implemented as *strictly local*. Proxies of this form consist of only local methods, each executing in the client's JVM. Unlike smart proxies, no remote invocations result when any method of a strictly local proxy is invoked.

Typically, Jini services provide a proxy having one of the forms described above. When a service registers with a lookup service, the service's proxy is copied (through serialization) into the lookup service. When a client looks up the service, the service's proxy is downloaded to the client. The client can then invoke the methods contained in the service's proxy. If the invoked method is a local method, then execution will occur in the JVM of the client. If the invoked method is a remote method (or results in a remote invocation), then execution is initiated in the client's JVM and, ultimately occurs in the JVM of the service.

Note that for the purposes of this document, the term *front-end proxy* (or simply, *front-end*) may be used interchangeably with the term proxy. Similarly, the term *back-end server* (or simply, *back-end*) may be used interchangeably with the term remote object. Thus, the back-end of a service is the part of the service's implementation that satisfies the contract advertised in the service's remote interface.

### 1.2.8 Activation

The glossary defines the term *active object* as a remote object that is instantiated and exported in a JVM on some system. Remote objects can be implemented with the ability to change their state from inactive to active, or from active to inactive;

the process of doing so is referred to as *activation* and *deactivation*, respectively. Many Jini services wishing to conserve computational resources may find this capability desirable. When the back-end of any Jini service is implemented with the ability to activate and deactivate, the service is referred to as an *activatable service*. Refer to the *Java™ Remote Method Invocation Specification* for the details of activation.

## 1.3 Utility Interfaces

This document specifies a set of general purpose utility interfaces collectively referred to as the *Discovery Management Interfaces*. This set currently consists of the following three interfaces:

- ◆ `DiscoveryManagement`
- ◆ `DiscoveryGroupManagement`
- ◆ `DiscoveryLocatorManagement`

These interfaces specify sets of methods that define a mechanism for managing various aspects of an entity's discovery duties. Because these interfaces provide a uniform way to define utility classes that perform discovery-related management duties on behalf of a client or service, a number of the helper utility classes specified in this document implement one or more of these interfaces.

## 1.4 Helper Utilities

This document specifies the following Jini technology helper utility classes:

- ◆ `LookupLocatorDiscovery`
- ◆ `LookupDiscoveryManager`
- ◆ `LeaseRenewalManager`
- ◆ `JoinManager`
- ◆ `ClientLookupManager`

### **1.4.1      The LookupLocatorDiscovery Utility**

The LookupLocatorDiscovery helper utility encapsulates the functionality required of an entity that wishes to employ the unicast discovery protocol to discover a Jini lookup service. This utility provides an implementation that makes the process of finding specific instances of the Jini lookup service much simpler for both services and clients.

### **1.4.2      The LookupDiscoveryManager**

The LookupDiscoveryManager is a helper utility class that organizes and manages all discovery-related activities on behalf of a Jini client or service. That is, rather than providing its own facility for coordinating and maintaining all of the necessary state information related to group names, locators, and `net.jini.discovery.DiscoveryListener` objects, the entity can employ this class to provide those facilities on its behalf.

### **1.4.3      The LeaseRenewalManager**

The LeaseRenewalManager helper utility class encapsulates functionality that provides for the coordination, systematic renewal, and overall management of a set of leases associated with some object on behalf of another object.

### **1.4.4      The JoinManager**

The JoinManager is a helper utility class that performs all of the functions related to discovery, joining, service lease renewal, and attribute management which the Jini technology programming model requires of a well-behaved Jini service.

### **1.4.5      The ClientLookupManager**

The ClientLookupManager class is a helper utility class that any client-like entity can use to create and populate a cache of service references, and with which the entity can register for notification of the availability of services of interest. Like the JoinManager utility class, this class needs to be notified when a desired lookup service is discovered. But unlike the JoinManager, the ClientLookupManager does not register the entity as a service with discovered lookup services. Although both the JoinManager and the ClientLookupManager perform lookup discovery event handling for the entities that employ them, the

`JoinManager` performs join processing for Jini services, while the `ClientLookupManager` performs service discovery and management processing both for clients and for services.

The `ClientLookupManager` class can be asked to “discover” services an entity is interested in using, and to cache the references to those services as each is found. The cache can be viewed as a set of services that the entity can access through a set of public, non-remote methods.

The `ClientLookupManager` class also provides a mechanism for an entity to request notification when a service of interest is discovered for the first time or has encountered a state change (such as removal from all lookup services or attribute set changes).

For convenience, the `ClientLookupManager` class also provides versions of a method named `lookup`, which employs invocation semantics similar to the semantics of the `lookup` method of the `ServiceRegistrar` interface, specified in the *Jini™ Lookup Service Specification*. Entities needing to find services on only an infrequent basis, or in which the cost of making a remote call is outweighed by the overhead of maintaining a local cache (e.g., due to limited resources), may find this method useful.

All three mechanisms described above — local queries on the cache, service discovery notification, and remote lookups — employ the same template-matching scheme as that described in the *Jini™ Lookup Service Specification*. Additionally, each mechanism allows the entity to supply an action object referred to as a *filter*. Such an object is a non-remote object that defines additional matching criteria that will be applied when searching for the entity’s services of interest. This filtering facility is particularly useful to entities that wish to extend the capabilities of the standard template-matching scheme.

## 1.5 Helper Services

This document specifies the following Jini technology helper services:

- ◆ `LookupDiscoveryService`
- ◆ `LeaseRenewalService`
- ◆ `EventMailbox`

### 1.5.1 The `LookupDiscoveryService`

Under certain circumstances, a discovering entity may find it useful to allow a third party to perform the entity’s discovery duties. For example, an activatable

entity that wishes to deactivate may wish to employ a special Jini service — referred to as the *lookup discovery service* — to perform discovery duties on behalf of the entity. Such an entity may wish to deactivate for various reasons, one being to conserve computational resources. While the entity is deactivated, the lookup discovery service, running on the same or a separate host, would employ the Jini discovery protocols to find lookup services in which the entity has expressed interest, and would notify the entity when a previously unavailable lookup service becomes available.

### 1.5.2 The LeaseRenewalService

The LeaseRenewalService is a Jini service that can be employed by both Jini clients and services to perform all lease renewal duties on their behalf. Services that wish to remain inactive until needed may find the LeaseRenewalService quite useful. Such a service can request that the LeaseRenewalService take on the responsibility of renewing the leases granted to the service, and then safely deactivate without risking the loss of access to the resources corresponding to the leases being renewed.

Clients that have continuous *access* to a network, but which cannot be continuously *connected* to that network (e.g., a cell phone), may also find this service useful. By allowing a LeaseRenewalService (which can be continuously connected) to renew the leases on the resources acquired by the client, the client may remain disconnected until needed. This removes the need to perform the discovery and lookup process each time the client re-connects to the network; possibly resulting in a significant increase in efficiency.

### 1.5.3 The EventMailbox

The EventMailbox service is a Jini service that can be employed by Jini clients and services to store event notifications on their behalf. When an entity registers with the EventMailbox service, that service will collect events intended for the registered entity until the entity initiates delivery of the events.

A service such as the EventMailbox can be particularly useful to entities that desire more control over the delivery of the events sent to them. Some entities operating in a distributed system may find it undesirable or inefficient to be contacted solely for the purpose of having an event delivered; preferring to defer the delivery to a time that is more convenient, as determined by the entity itself.

For example, an entity wishing to deactivate or detach from a network may wish to have its events stored until the entity is available to retrieve them. Additionally, some entities may wish to batch process event notifications for efficiency.

In both scenarios, the entities described may find the EventMailbox service useful in achieving the respective event delivery goals.

## 1.6 Dependencies

This specification relies on the following specifications:

- ◆ *Java™ Remote Method Invocation Specification*
- ◆ *Java™ Object Serialization Specification*
- ◆ *Jini™ Technology Glossary*
- ◆ *Jini™ Distributed Event Specification*
- ◆ *Jini™ Distributed Leasing Specification*
- ◆ *Jini™ Discovery and Join Specification*
- ◆ *Jini™ Discovery Utilities Specification*
- ◆ *Jini™ Lookup Service Specification*
- ◆ *Jini™ Lookup Attribute Schema Specification*
- ◆ *Jini™ Transaction Specification*

---

# The Discovery Management Interfaces

## 2.1 Overview

Discovery is one behavior that is common to all entities wishing to interact with a Jini lookup service. Whether an entity is a client, a service, or a service acting as a client, before the entity can begin interacting with a Jini lookup service, the entity must first discover that lookup service.

The interfaces referred to collectively as the *discovery management* interfaces specify sets of methods that define a mechanism that may be used to manage various aspects of the discovery duties of entities that wish to participate in a Jini application environment. These interfaces provide a uniform way to define utility classes that perform the necessary discovery-related management duties on behalf of a client or service. Currently, there are three discovery management interfaces (belonging to the package `net.jini.discovery`):

- ◆ `DiscoveryManagement`
- ◆ `DiscoveryGroupManagement`
- ◆ `DiscoveryLocatorManagement`

The `DiscoveryManagement` interface defines semantics for methods related to the discovery event mechanism and discovery process termination. Through this interface an entity can register or un-register for discovery events, discard a lookup service, or terminate the discovery process.

The `DiscoveryGroupManagement` interface defines methods related to the management of the sets of lookup services that are to be discovered using the multicast discovery protocol (as defined in the *Jini™ Discovery and Join Specifica-*

tion). The methods of this interface define how an entity accesses or modifies the contents of the set containing the names of the groups whose members are lookup services the entity is interested in discovering through group discovery.

The `DiscoveryLocatorManagement` interface defines methods related to the management of the set of lookup services that are to be discovered using the unicast discovery protocol (as defined in the *Jini™ Discovery and Join Specification*). The methods of this interface define how an entity accesses or modifies the contents of the set of `LookupLocator` objects corresponding to the specific lookup services the entity has targeted for locator discovery.

Although each interface defines semantics for methods involved in the management of the discovery process, the individual roles each interface plays in that process are independent of each other. Because of this independence, there may be scenarios where it is desirable to implement some subset of these interfaces.

For example, a class may wish to implement the functionality defined in `DiscoveryManagement`, but may not wish to allow entities to modify the groups and locators associated with the lookup services to be discovered. Such a class may have a “hard-coded” list of the groups and locators that it internally registers with the discovery process. For this case, the class would implement only `DiscoveryManagement`.

Alternatively, another class may not wish to allow the entity to register more than one listener with the discovery event mechanism; nor may it wish to allow the entity to terminate discovery. It may simply wish to allow the entity to modify the sets of lookup services that will be discovered. A class such as this would implement both `DiscoveryGroupManagement` and `DiscoveryLocatorManagement`, but not `DiscoveryManagement`.

A specific example of a class that implements only a subset of the set of interfaces specified here is the `LookupDiscovery` utility class (defined in the *Jini™ Discovery Utilities Specification*). That class implements both the `DiscoveryManagement` and `DiscoveryGroupManagement` interfaces, but not the `DiscoveryLocatorManagement` interface.

Throughout this chapter, the phrase *implementation class* refers to any concrete class which implements one or more of the discovery management interfaces, and the phrase *implementation object* should be understood as an instance of such an implementation class. Additionally, whenever a description refers to the *discovering entity* (or simply, the *entity*), that phrase should be taken to mean the object (the client or service) that has created an implementation object; and which wishes to avail itself of the public methods specified by these interface(s) and provided by that object.

## 2.2 Other Types

The types defined in the specification of the discovery management interfaces are in the `net.jini.discovery` package. The following types may be referenced in this chapter. Whenever referenced, these object types will be referenced in unqualified form:

```
net.jini.core.discovery.LookupLocator  
net.jini.core.lookup.ServiceRegistrar  
java.io.IOException
```

## 2.3 The DiscoveryManagement Interface

The public methods specified by the `DiscoveryManagement` interface are as follows:

```
package net.jini.discovery;  
  
public interface DiscoveryManagement  
{  
    public void addDiscoveryListener  
                                   (DiscoveryListener listener);  
    public void removeDiscoveryListener  
                                   (DiscoveryListener listener);  
  
    public ServiceRegistrar[] getRegistrars();  
  
    public void discard(ServiceRegistrar proxy);  
    public void terminate();  
}
```

### 2.3.1 The Semantics

The `DiscoveryManagement` interface defines methods related to the discovery event mechanism and discovery process termination. Through this interface an entity can register or un-register `DiscoveryListener` objects to receive discovery events (instances of `DiscoveryEvent`), retrieve proxies to the currently discovered lookup services, discard a lookup service so that it is eligible for re-discovery, or terminate the discovery process.

Implementation classes of this interface may impose additional semantics on any method. For example, such a class may choose to require that rather than simply terminate discovery processing, the `terminate` method additionally cancel all leases held by the implementation object and terminate all lease management being performed on behalf of the entity.

For information on any additional semantics imposed on a method of this interface, refer to the specification of the particular implementation class.

Note that `DiscoveryEvent` and `DiscoveryListener` are both defined in the *Jini™ Discovery Utilities Specification*.

- ◆ The `addDiscoveryListener` method adds a listener to the set of objects listening for discovery events. This method takes a single argument as input: an instance of `DiscoveryListener` corresponding to the listener to add to the set.

Once a listener is registered, it will be notified of all lookup services discovered to date, and will then be notified as new lookup services are discovered or existing lookup services are discarded.

If `null` is input to this method, no action will be taken. If the listener input to this method duplicates (using the `equals` method) another element in the set of listeners, no action is taken.

- ◆ The `removeDiscoveryListener` method removes a listener from the set of objects listening for discovery events. This method takes a single argument as input: an instance of `DiscoveryListener` corresponding to the listener to remove from the set.

If the listener object input to this method does not exist in the set of listeners maintained by the implementation class, then this method will take no action.

---

**Note:** Should pending events be addressed with respect to invocations of `removeDiscoveryListener`? For example, should a requirement like the following be made: “Once an invocation of `removeDiscoveryListener` returns, it is guaranteed that none of the removed listener(s) will receive any pending notification events.” This question is asked because some of the current implementations of the discovery management interfaces (e.g., `LookupDiscovery`, `LookupLocatorDiscovery`, `LookupDiscoveryManager`) queue the references to the listeners along with the pending events (for efficiency). So, even if a listener is removed, a reference to it still exists in the event queue; and the listener may be notified when the event finally gets to the front of the queue. So should

this requirement be specified — forcing existing implementations to be changed  
— or is it too implementation specific to include here?

---

- ◆ The `getRegistrars` method returns an array consisting of instances of the `ServiceRegistrar` interface. Each element in the returned set is a proxy to one of the currently discovered lookup services. Each time this method is invoked, a new array is returned; if no lookup services have been discovered, an empty array is returned. This method takes no arguments as input.
- ◆ The `discard` method removes a particular lookup service from the managed set of lookup services, and makes that lookup service eligible to be re-discovered. This method takes a single argument as input: an instance of the `ServiceRegistrar` interface corresponding to the proxy to the lookup service to discard.

If the proxy input to this method is `null`, or if it matches (using the `equals` method) none of the lookup services in the managed set, this method takes no action.

Note that once a lookup service is discovered, there is no requirement for ongoing communication between the discovered lookup service and the implementation object. This means that if a lookup service goes away, there may be no automatic notification of the occurrence of such an event. Thus, if an entity encounters an unavailable lookup service, it is the responsibility of the entity to invoke the `discard` method.

Invoking the `discard` method defined by the `DiscoveryManagement` interface will result in the flushing of the lookup service from the appropriate cache, ultimately causing a discard notification to be sent to all `DiscoveryListener` objects registered with the implementation object. The lookup service is guaranteed to have been removed from the managed set when this method completes successfully; the lookup service is then said to have been “discarded”. No such guarantee is made with respect to when the discard event is sent to the registered listeners. That is, the event notifying the listeners that the service has been discarded may or may not be sent asynchronously.

- ◆ The `terminate` method ends all discovery processing being performed on behalf of the entity. This method takes no input arguments.

After this method has been invoked, no new lookup services will be discovered, and the effect of any new operations performed on the current implementation object are undefined.

Any additional termination semantics must be defined by the implementation class.

## 2.4 The `DiscoveryGroupManagement` Interface

The public methods specified by the `DiscoveryGroupManagement` interface are as follows:

```
package net.jini.discovery;

public interface DiscoveryGroupManagement
{
    public static final String[] ALL_GROUPS = null;
    public static final String[] NO_GROUPS = new String[0];

    public String[] getGroups();
    public void addGroups(String[] groups) throws IOException;
    public void setGroups(String[] groups) throws IOException;
    public void removeGroups(String[] groups);
}
```

### 2.4.1 The Semantics

The `DiscoveryGroupManagement` interface defines methods and constants related to the management of the sets of lookup services that are to be discovered using the multicast discovery protocol; that is, lookup services that are discovered by way of group discovery. The methods of this interface define how an entity retrieves or modifies the set of groups associated with those lookup services.

The methods that modify the managed set of groups each take a single input parameter: a `String` array, none of whose elements may be `null`. Each of these methods throws a `NullPointerException` when at least one element of the input array is `null`.

The empty set is denoted by the empty array, and “no set” is indicated by `null`. Invoking any of these methods with an input array that contains duplicate group names is equivalent to performing the invocation with the duplicates removed from the array.

The `ALL_GROUPS` and the `NO_GROUPS` constants are defined for convenience, and represent no set and the empty set respectively. The `ALL_GROUPS` constant can be passed to the `setGroups` method to request that attempts be made to discover all lookup services that are within range, and which belong to any group. The

NO\_GROUPS constant can be used to request that discovery by group membership be halted until another call to `setGroups` is made.

- ◆ The `getGroups` method returns an array consisting of the names of the groups in the managed set. If the managed set of groups is empty, this method will return the empty array. If there is no managed set of groups, then `null` (ALL\_GROUPS) is returned; indicating that all groups are to be discovered. If the empty array is returned, that array is guaranteed to be referentially equal to the NO\_GROUPS constant; that is, the array returned from that method and the NO\_GROUPS constant can be tested for equality using the `==` operator.

This method takes no arguments as input and, provided the managed set of groups currently exists, will return a new array upon each invocation.

- ◆ The `addGroups` method adds a set of group names to the managed set. The array input to this method contains the group names that are to be added.

Elements in the input set that duplicate elements already in the managed set will be ignored. Once a new name is added to the managed set, attempts will be made to discover all (as yet) undiscovered lookup services that are members of the group having that name.

The entity must have `DiscoveryPermission` on each of the groups in the new set or a `SecurityException` will be propagated through this method.

This method throws `IOException` because an invocation of this method may result in the re-initiation of the discovery process, which can throw `IOException` when socket allocation occurs.

This method throws an `UnsupportedOperationException` if there is no managed set of groups to augment. If `null` (ALL\_GROUPS) is input, this method throws a `NullPointerException`. If the empty array (NO\_GROUPS) is input, the managed set of groups will not change.

- ◆ The `setGroups` method replaces all of the group names in the managed set with names from a new set. The array input to this method contains the group names that will replace the current names in the managed set.

Once a new group name has been placed in the managed set, if there are lookup services belonging to that group that have already been discovered, no event will be sent to the entity's listener for those particular lookup services. Attempts to discover all (as yet) undiscovered lookup services belonging to that group will continue to be made.

If `null` (`ALL_GROUPS`) is input to `setGroups`, then attempts will be made to discover all (as yet) undiscovered lookup services located within the *multi-cast radius* of the implementation object. If the empty array (`NO_GROUPS`) is input, then group discovery will cease.

The entity must have `DiscoveryPermission` on each of the groups in the new set or a `SecurityException` will be propagated through this method.

This method throws `IOException`. This is because an invocation of this method may result in the re-initiation of the discovery process, a process that can throw `IOException` when socket allocation occurs.

- ◆ The `removeGroups` method deletes a set of group names from the managed set of groups. The array input to this method contains the group names that will be removed from the managed set.

This method throws an `UnsupportedOperationException` if there is no managed set of groups from which to remove elements. If `null` (`ALL_GROUPS`) is input to `removeGroups`, a `NullPointerException` will be thrown. For any element in the input set that equals no element in the managed set, `removeGroups` takes no action with respect to that element. If the empty array (`NO_GROUPS`) is input, the managed set of groups will not change.

Any already-discovered lookup service that is a member of one or more group(s) removed from the managed set by either `setGroups` or `removeGroups` will be discarded and will not be eligible for discovery; but only if it satisfies both of the following conditions:

- the lookup service is not a member of any group in the new managed set resulting from the invocation of `setGroups` or `removeGroups`, and
- the lookup service is not currently eligible for discovery through other means (such as locator discovery).

## 2.5 The DiscoveryLocatorManagement Interface

The public methods specified by the `DiscoveryLocatorManagement` interface are as follows:

```
package net.jini.discovery;

public interface DiscoveryLocatorManagement
{
```

```
    public LookupLocator[] getLocators();  
    public void addLocators(LookupLocator[] locators);  
    public void setLocators(LookupLocator[] locators);  
    public void removeLocators(LookupLocator[] locators);  
}
```

### 2.5.1 The Semantics

The `DiscoveryLocatorManagement` interface defines methods related to the management of the set of lookup services that are to be discovered using the unicast discovery protocol; that is, lookup services that are discovered by way of locator discovery. The methods of this interface define how an entity retrieves or modifies the set of locators associated with those lookup services.

The methods that modify the managed set of locators each take a single input parameter: an array of locators, none of whose elements may be `null`. Each of these methods throws a `NullPointerException` when at least one element of the input array is `null`.

Invoking any of these methods with an input array that contains duplicate locators (as determined by the `LookupLocator.equals` method) is equivalent to performing the invocation with the duplicates removed from the array.

- ◆ The `getLocators` method returns an array containing the set of `LookupLocator` objects in the managed set of locators. The returned set will include both the set of `LookupLocator` objects corresponding to lookup services that have already been discovered as well as the set of those that have not yet been discovered. If the managed set is empty, this method will return the empty array. This method takes no arguments as input, and will return a new array upon each invocation.
- ◆ The `addLocators` method adds a set of locators to the managed set. The array input to this method contains the set of `LookupLocator` objects that will be added to the managed set. Elements in the input set that duplicate (using the `LookupLocator.equals` method) elements already in the managed set will be ignored.

This method throws an `UnsupportedOperationException` if there is no managed set of locators to augment. If `null` is input to `addLocators`, a `NullPointerException` will be thrown. If the empty array is input, the managed set of locators will not change.

- ◆ The `setLocators` method replaces all of the locators in the managed set with `LookupLocator` objects from a new set. The array input to this method contains the set of `LookupLocator` objects that will replace the locators in the managed set.

If `null` is input to `setLocators`, a `NullPointerException` will be thrown. If the empty array is input, locator discovery will cease.

- ◆ The `removeLocators` method deletes a set of locators from the managed set. The array input to this method contains the set of `LookupLocator` objects that will be removed from the managed set.

This method throws an `UnsupportedOperationException` if there is no managed set of locators from which to remove elements. If `null` is input to `removeLocators`, a `NullPointerException` will be thrown. For any element in the input set that equals no element in the managed set, `removeLocators` takes no action with respect to that element. If the empty array is input, the managed set of locators will not change.

Any already-discovered lookup service will be discarded and will not be eligible for discovery if it corresponds to a locator that is removed from the managed set by either `setLocators` or `removeLocators`; but only if it is not currently eligible for discovery through other means (such as group discovery).

---

# The LookupLocatorDiscovery Utility

## 3.1 Overview

The *Jini™ Discovery and Join Specification* states that the “unicast discovery protocol is a simple request-response protocol”. In a Jini application environment, the entities that participate in this protocol are a *discovering entity* (Jini client or service) and a Jini lookup service which acts as the entity that is to be discovered. The discovering entity sends unicast discovery requests to the lookup service; and the lookup service reacts to those requests by sending unicast discovery responses to the interested discovering entity.

The `LookupLocatorDiscovery` helper utility (belonging to the package `net.jini.discovery`) encapsulates the functionality required of an entity that wishes to employ the unicast discovery protocol to discover a Jini lookup service. This utility provides an implementation that makes the process of finding specific instances of the Jini lookup service much simpler for both services and clients.

Because the `LookupLocatorDiscovery` helper utility class will participate in only the unicast discovery protocol, and because the unicast discovery protocol imposes no restriction on the physical location of a service or client relative to a lookup service, this utility can be used to discover lookup services running on hosts that are located far from, or near to, the hosts on which the service is running. This lack of a restriction on location brings with it a requirement that the discovering entity supply specific information about the desired lookup services to the `LookupLocatorDiscovery` utility; namely, the location of the device(s) host-

ing each lookup service. This information is supplied through an instance of the LookupLocator utility, defined in the *Jini™ Discovery and Join Specification*.

It may be of value to note the difference between LookupLocatorDiscovery and the utility LookupDiscovery defined in the *Jini™ Discovery Utilities Specification*. Although both are non-remote utility classes that entities can use to discover at least one lookup service, the LookupLocatorDiscovery utility is designed to provide discovery capabilities that satisfy different needs than those satisfied by the LookupDiscovery utility. These two utilities differ in the following ways:

- ◆ Whereas the LookupLocatorDiscovery utility is used to discover lookup services by their *locators*, employing the unicast discovery protocol, the LookupDiscovery utility uses the multicast discovery protocol to discover lookup services by the *groups* to which the lookup services belong.
- ◆ Whereas the LookupLocatorDiscovery utility requires that the discovering entity supply the specific location — or address — of the desired lookup service(s) in the form of a LookupLocator object, the LookupDiscovery utility imposes no such restriction on the discovering entity.
- ◆ Whereas the LookupLocatorDiscovery utility can be used by a discovering entity to discover lookup services that are both “near” and “far”, the LookupDiscovery utility can be used to discover only those lookup services that are located within the same *multicast radius* as that of the discovering entity.

## 3.2 Other Types

The types defined in the specification of the LookupLocatorDiscovery utility class are in the `net.jini.discovery` package. The following types may be referenced in this chapter. Whenever referenced, these object types will be referenced in unqualified form:

```
net.jini.core.discovery.LookupLocator  
net.jini.discovery.DiscoveryManagement  
net.jini.discovery.DiscoveryLocatorManagement  
net.jini.discovery.LookupDiscovery
```

### 3.3 The Interface

The public methods provided by the `LookupLocatorDiscovery` class are as follows:

```
package net.jini.discovery;

public class LookupLocatorDiscovery
    implements DiscoveryManagement
               DiscoveryLocatorManagement
{
    public LookupLocatorDiscovery(LookupLocator[] locators);

    public LookupLocator[] getDiscoveredLocators();
    public LookupLocator[] getUndiscoveredLocators();
}
```

### 3.4 The Semantics

Each instance of the `LookupLocatorDiscovery` class must behave as if it operates independently of all other instances.

The `equals` method for this class returns `true` if and only if two instances of this class refer to the same object. That is, `x` and `y` are equal instances of this class if and only if `x == y` has the value `true`.

- ◆ The constructor of the `LookupLocatorDiscovery` class takes a single input parameter: a set of locators, none of whose elements may be `null`. Each element in the input set corresponds to a specific lookup service the discovering entity wishes to be discovered. If at least one element of the input array is `null`, a `NullPointerException` is thrown. This set is represented as an array of `LookupLocator` objects.

Invoking the constructor with an input array that contains duplicate locators (as determined by `LookupLocator.equals`) is equivalent to performing the invocation with the duplicates removed from the array.

Discovery typically starts as soon as an instance of this class is created, and ends when the `terminate` method is called. However, if `null` or the empty set is passed to the constructor, discovery will not be started until the `setLocators` method is called with a non-empty set.

- ◆ The `getDiscoveredLocators` method returns the set of `LookupLocator` objects representing the desired lookup services that are currently discovered. If the set is empty, this method will return the empty array. This method takes no arguments as input, and will return a new array upon each invocation.
- ◆ The `getUndiscoveredLocators` method returns the set of `LookupLocator` objects representing the desired lookup services that have not yet been discovered. If the set is empty, this method will return the empty array. This method takes no arguments as input, and will return a new array upon each invocation.

## 3.5 Supporting Interfaces

The `LookupLocatorDiscovery` utility class depends on the following interfaces: `DiscoveryManagement` and `DiscoveryLocatorManagement`.

### 3.5.1 The `DiscoveryManagement` Interfaces

The `LookupLocatorDiscovery` class implements both the `DiscoveryManagement` and the `DiscoveryLocatorManagement` interfaces, which together define methods related to the coordination and management of all discovery processing. Refer to the chapter of this specification titled *The Discovery Management Interfaces*.

The `LookupLocatorDiscovery` class defines no additional semantics for any method specified by either of these interfaces.

---

# The LookupDiscoveryManager

## 4.1 Overview

Although the goals of any well-behaved Jini client or service are application-specific, the goals of such entities with respect to their interaction with Jini lookup services generally begin with employing the Jini discovery protocols (defined in the *Jini™ Discovery and Join Specification*) to obtain a reference to at least one Jini lookup service. Because the discovery duties performed by such entities may require the management of significant amounts of state information, those duties can become quite tedious.

The `LookupDiscoveryManager` is a helper utility class (belonging to the package `net.jini.discovery`) that organizes and manages all discovery-related activities on behalf of a Jini client or service. Rather than providing its own facility for coordinating and maintaining all of the necessary state information related to group names, `LookupLocator` objects, and `DiscoveryListener` objects, such entities can employ this class to provide those facilities on its behalf.

Note that throughout this specification, two terms will be used interchangeably when referring to Jini clients and services that create an instance of the `LookupDiscoveryManager` and avail themselves of that class' methods. Those terms are: the *discovering entity* or simply, the *entity*.

## 4.2 Other Types

The types defined in the specification of the `LookupDiscoveryManager` utility class are in the `net.jini.discovery` package. The following types may be refer-

enced in this chapter. Whenever referenced, these object types will be referenced in unqualified form:

```
net.jini.core.discovery.LookupLocator
net.jini.core.lookup.ServiceRegistrar
net.jini.discovery.DiscoveryEvent
net.jini.discovery.DiscoveryListener
net.jini.discovery.DiscoveryManagement
net.jini.discovery.DiscoveryGroupManagement
net.jini.discovery.DiscoveryLocatorManagement
java.io.IOException
java.util.EventListener
java.util.EventObject
```

### 4.3 The Interface

The only new public method of the `LookupDiscoveryManager` utility class is the constructor. All other public methods implemented by this class are specified in the discovery management interfaces.

```
package net.jini.discovery;

public class LookupDiscoveryManager
    implements DiscoveryManagement,
               DiscoveryGroupManagement,
               DiscoveryLocatorManagement
{
    public LookupDiscoveryManager(String[] groups,
                                   LookupLocator[] locators,
                                   DiscoveryListener listener)
        throws IOException;
}
```

### 4.4 The Semantics

The `equals` method for this class returns `true` if and only if two instances of this class refer to the same object. That is, `x` and `y` are equal instances of this class if and only if `x == y` has the value `true`.

- ◆ The constructor for the `LookupDiscoveryManager` takes the following arguments as input:
  - A `String` array, none of whose elements may be `null`, and in which each element is the name of a group whose members are lookup services the entity wishes to be discovered via group discovery
  - An array of `LookupLocator` objects, none of whose elements may be `null`, and in which each element corresponds to a specific lookup service the entity wishes to be discovered via locator discovery
  - A reference to a `DiscoveryListener` object that will be notified when a targeted lookup service is discovered or discarded

The `LookupDiscoveryManager` will, on behalf of the client, employ the Jini discovery protocols defined in the *Jini™ Discovery and Join Specification* to find the lookup services associated with the first two arguments, and will maintain and manage the discovered lookup services from both the input set of groups and the input set of locators.

If `null` is input to the `groups` argument, then attempts will be made via group discovery to discover all lookup services located within the *multicast radius* of the entity that constructs an instance of this class. If the empty array is input to the `groups` argument, no lookup service will be discovered via group discovery. If at least one element of the `groups` argument is `null`, a `NullPointerException` is thrown.

If an empty or `null` array is input to the `locators` argument, no attempt will be made to discover specific lookup services via locator discovery. If at least one element of the `locators` argument is `null`, a `NullPointerException` is thrown.

If the constructor is invoked with a set of group names and a set of locators in which either or both sets contain duplicate elements (where duplicate locators are determined by calling the `LookupLocator.equals` method), the invocation is equivalent to constructing an instance of `LookupDiscoveryManager` with no duplicates in either set.

The last argument to the constructor is a reference to a listener object that will be registered to receive discovery event notifications. If a `null` reference is input to this argument, then the client will receive no discovery events. It is the responsibility of the client to create and pass into the `LookupDiscoveryManager` an object that implements the `DiscoveryListener` interface. That implementation must provide the definition of the actions to take upon receipt of any notifications.

This constructor throws `IOException`. This is because construction of a `LookupDiscoveryManager` may initiate the multicast discovery process, a process that can throw `IOException`.

## 4.5 Supporting Interfaces and Classes

The `LookupDiscoveryManager` depends on the following interfaces: `DiscoveryManagement`, `DiscoveryGroupManagement`, `DiscoveryLocatorManagement`, and `DiscoveryListener`. This class also depends (indirectly) on one concrete class: `DiscoveryEvent`.

The `DiscoveryListener` interface and the `DiscoveryEvent` class are both defined in the *Jini™ Discovery Utilities Specification*.

### 4.5.1 The DiscoveryManagement Interfaces

The `LookupDiscoveryManager` implements the `DiscoveryManagement`, `DiscoveryGroupManagement`, and `DiscoveryLocatorManagement` interfaces which together define methods related to the coordination and management of all discovery processing. Those interfaces are defined in the chapter of this specification titled *The Discovery Management Interfaces*. The `LookupDiscoveryManager` class defines no additional semantics for any method specified by the discovery management interfaces.

### 4.5.2 The DiscoveryListener Interface

The `DiscoveryListener` interface defines the mechanism through which an entity receives notification from discovery utility objects such as `LookupDiscovery` or `LookupLocatorDiscovery` that a lookup service has been discovered or discarded. This interface is specified in the *Jini™ Discovery Utilities Specification*.

### 4.5.3 The DiscoveryEvent Class

The `DiscoveryEvent` class defines the object passed to interested entities to indicate that one or more `ServiceRegistrar` objects (lookup services) have been discovered or discarded by a discovery utility object such as `LookupDiscovery` or `LookupLocatorDiscovery`. This interface is specified in the *Jini™ Discovery Utilities Specification*.

---

# The LeaseRenewalManager

## 5.1 Overview

The `LeaseRenewalManager` helper utility class (belonging to the package `net.jini.lease`) encapsulates functionality which provides for the coordination, systematic renewal, and overall management of a set of leases associated with some object on behalf of another object.

The concept of *leased* resources is fundamental to the Jini technology programming model. Providing a leasing mechanism helps to prevent the accumulation of outdated and unwanted resources in time-based distributed systems such as the Jini technology infrastructure. The leasing model for Jini technology, defined in the *Jini™ Distributed Leasing Specification*, requires renewed proof of interest to continue the existence of a leased resource. Thus, any Jini client or service that requests the use of the leased resources provided by another Jini service may be granted access to those resources for a negotiated period of time; and must continue to request renewal of the lease on each resource for as long as the client or service wishes to have access to the resource.

For example, the Jini lookup service leases two resources: residency in its database and registration with its event notification mechanism. Thus, if a service that is registered with a Jini lookup service wishes to continue its residency beyond the length of the current lease, the service must request a lease renewal from that lookup service. This renewal process must be repeated for as long as the service wishes to maintain its residency in the lookup. Similarly, if a registered service has requested that the lookup service notify it of events of interest, then prior to the expiration of the lease on the event mechanism, the service must request that the lookup service continue to send such events. As with residency in the lookup service, these renewal requests must be repeated for as long as the service wishes to receive event notifications.

Another example of a Jini service providing leased resources would be a service that implements the *Jini™ Transaction Specification* to manage transactions

```

    public void renewUntil(Lease lease,
                           long expiration,
                           LeaseListener listener);
    public void renewFor(Lease lease,
                        long duration,
                        LeaseListener listener);

    public long getExpiration(Lease lease)
        throws UnknownLeaseException;
    public void setExpiration(Lease lease, long expiration)
        throws UnknownLeaseException;
    public void remove(Lease lease)
        throws UnknownLeaseException;
    public void cancel(Lease lease)
        throws UnknownLeaseException, RemoteException;
    public void clear();
}

```

## 5.4 The Semantics

This class distinguishes between two time values associated with lease expiration: the *desired* time of expiration for the lease; and the *actual* time of expiration granted when the lease is created or renewed. Both time values are absolute times, not relative time durations. The actual expiration time of a lease object can be retrieved by invoking the `getExpiration` method on the lease (see the `Lease` interface defined in the *Jini™ Distributed Leasing Specification*).

Methods of this class that accept `Lease.FOREVER` or `Lease.ANY` as the desired expiration time will treat `Lease.FOREVER` and `Lease.ANY` as semantically identical. That is, if either `Lease.FOREVER` or `Lease.ANY` is requested, renewal requests will be made indefinitely until a cancellation request is made. Although these values are not distinguished in the semantics of the `LeaseRenewalManager` itself, they may ultimately be distinguished in the semantics of the entity that granted the lease. Whenever the `LeaseRenewalManager` requests that a lease-granting entity renew a lease to expire at some absolute time, the value of the desired lease expiration time (whatever that value may be — `Lease.FOREVER`, `Lease.ANY`, or any other value) will be passed on to that lease-granting entity, leaving it to the lease-granting entity to define the semantics of the requested lease expiration time.

The `LeaseRenewalManager` makes certain concurrency guarantees. When the `LeaseRenewalManager` makes a remote call (for example, when requesting the

renewal of a lease), any invocations made on the methods of the LeaseRenewalManager will not be blocked.

Similarly, the LeaseRenewalManager makes a re-entrancy guarantee with respect to LeaseListener objects registered with the LeaseRenewalManager. Should the LeaseRenewalManager invoke a method on a registered listener (a local call), calls from that method to any method of the LeaseRenewalManager are guaranteed not to result in a deadlock condition.

The equals method for this class returns true if and only if two instances of this class refer to the same object. That is, `x` and `y` are equal instances of this class if and only if `x == y` has the value true.

The individual semantics of each method of this class are described below.

◆ The constructor has two forms:

- The first form of the constructor takes no arguments. This form of the constructor instantiates a LeaseRenewalManager object that initially manages no leases.
- The second form of the constructor creates a LeaseRenewalManager that initially manages a single lease. This form of the constructor requires that a reference to the initial lease be supplied as an argument.

This constructor also takes an expiration argument that represents the *desired* (absolute) time of expiration for the lease, and a reference to a LeaseListener object that receives notifications of exceptional conditions occurring during renewal attempts.

Creating a LeaseRenewalManager using this form of the constructor is equivalent to invoking the no-argument constructor followed by an invocation of the `renewUntil` method (described later).

- ◆ The `renewUntil` method adds a lease to the set of leases being managed by the LeaseRenewalManager. This method takes as arguments a reference to the lease to manage, the desired time of expiration of the lease, and a reference to the LeaseListener object that will receive notification of exceptional conditions when attempting lease renewal. A value of `Lease.ANY` or `Lease.FOREVER` may be passed as the value of the expiration argument, and the LeaseListener argument may be null.

If the lease input to this method is already in the set of managed leases, the listener object and the desired expiration associated with that lease will be replaced with the new listener and expiration. The lease will remain in the set of managed leases until one of the following occurs:

- The lease expires
- The lease is cancelled
- An explicit removal of the lease from the set is requested
- An `UnknownLeaseException`, a `LeaseDeniedException`, or any other non-remote exception is received during a lease renewal attempt
- A (remote) `NoSuchObjectException` is received during a lease renewal attempt

If `null` is passed as the `lease` parameter, a `NullPointerException` will be thrown.

This method will interpret the value of the `expiration` parameter as the *desired* absolute system time after which the lease is no longer valid. This argument provides the ability to indicate an expiration time that extends beyond the actual expiration of the lease. If the value input to this argument does indeed extend beyond the actual lease expiration time, then the lease will be systematically renewed at appropriate times until one of the conditions listed above occurs. If the value input is less than or equal to the actual expiration time, nothing will be done to modify the time when the lease actually expires. That is, the lease will *not* be renewed with an expiration time that is less than the originally granted expiration.

If a non-`null` object reference is passed in as the `LeaseListener` parameter, the object will receive notification of exceptional conditions occurring upon a renewal attempt. In particular, exceptional conditions may include `UnknownLeaseException`, `LeaseDeniedException`, and `RemoteException`, as well as any other non-`RemoteException`.

If either an `UnknownLeaseException` or a `LeaseDeniedException` occurs during a lease renewal request, the event will be wrapped in an instance of the `LeaseRenewalEvent` class (described later) and sent to the listener.

If a `RemoteException` occurs during a renewal request for a particular lease, renewal requests will continue to be made for that lease until either the lease is renewed, or the lease expiration time has been exceeded. In the latter case, the first `RemoteException` received will be passed on to the `LeaseListener`.

If `null` is passed in as the `LeaseListener` parameter, the entity will receive no notification of exceptional conditions occurring as a result of a lease renewal attempt.

- ◆ The `renewFor` method adds a lease to the set of leases being managed by the `LeaseRenewalManager`. This method takes as input a reference to the lease to manage, a `long` value representing the desired duration of the lease, and a reference to a `LeaseListener` object that will receive notifications of exceptional conditions when attempting lease renewal.

The semantics of this method are identical to those of the `renewUntil` method described above, with the expiration parameter of `renewUntil` set to a value of *duration + current time* (in milliseconds).

This method tests for arithmetic overflow in the expiration time computed from the value of `duration` parameter (`current time + duration`). Should such overflow be present, a value of `Lease.FOREVER` is used to represent the lease's expiration time.

- ◆ The `getExpiration` method returns the current desired time of expiration requested for a particular lease, not the actual expiration that was granted when the lease was created or renewed. The only argument to this method is the reference to the lease object. If the lease is not in the set of managed leases, an `UnknownLeaseException` will be thrown.
- ◆ The `setExpiration` method replaces the current desired expiration of a given lease contained in the set of managed leases with a new desired expiration time. The only arguments to this method are the reference to the lease object and the new expiration time.

An invocation of this method with a lease that is currently a member of the managed set is equivalent to an invocation of the `renewUntil` method with the lease's current listener input to the `listener` parameter. In particular, if the value of the expiration parameter is less than or equal to the lease's current desired expiration, this method takes no action.

An invocation of this method with a lease that is not in the set of managed leases, will result in an `UnknownLeaseException`.

- ◆ The `remove` method removes a given lease from the set of managed leases. The only argument to this method is the reference to the lease object. If the lease is not in the set of managed leases, an `UnknownLeaseException` will be thrown.

Note that this method does not cancel the given lease; activities such as lease cancellation are left to the entity itself to manage.

- ◆ The `cancel` method both removes a given lease from the set of managed leases and cancels the given lease. The only argument to this method is the reference to the lease object. If the lease is not in the set of managed leases, an `UnknownLeaseException` will be thrown.

Any exception (remote or non-remote) occurring during the cancellation of the lease will have no effect on the removal of the lease from the managed set. That is, even if an exception occurs during the `cancel` operation, the lease must have been removed from the managed set upon return from this method.

Any exception thrown by the `cancel` method of the lease object itself may also be thrown by this method.

- ◆ The `clear` method removes all leases from the set of managed leases. It does not request the cancellation of those leases. This method takes no arguments.

## 5.5 Supporting Interfaces and Classes

The `LeaseRenewalManager` utility class depends on one interface: `LeaseListener`, which references one class, `LeaseRenewalEvent`.

### 5.5.1 The `LeaseListener` Interface

The `LeaseListener` interface defines the mechanism through which an entity receives notification that the `LeaseRenewalManager` has failed to renew one of the leases the `LeaseRenewalManager` is managing for the entity. Such renewal failures typically occur because of one of the following conditions:

- ◆ The expiration time of the lease has been reached, and the lease has already expired, before the renewal request can be made
- ◆ The renewal request has been denied by the lease grantor for some reason, even though the desired absolute expiration time of the lease has not yet been reached
- ◆ The renewal request could not be completed before the expiration of the lease

It is the responsibility of the entity to pass into the `LeaseRenewalManager` a reference to an object that implements the `LeaseListener` interface, which defines the actions to take upon receipt of a notification. When either of the above events occurs, the `LeaseRenewalManager` will send an instance of `LeaseRenewalEvent` to that listener object.

```
package net.jini.lease;
```

```
public interface LeaseListener extends EventListener
```

```
{  
    void notify(LeaseRenewalEvent e);  
}
```

### The Semantics

The `notify` method is invoked by the `LeaseRenewalManager` when it fails to renew a lease for an entity because one of the conditions described above has occurred. This method takes one parameter: an instance of the `LeaseRenewalEvent` class containing information about the lease on which the failed renewal attempt was made, as well as information about the condition that caused the renewal attempt to fail.

Note that prior to invoking this method, the `LeaseRenewalManager` removes the affected lease from the managed set of leases. Note also that because of the re-entrancy guarantee made by the `LeaseRenewalManager`, new leases can be safely added from within any listeners that implement this interface.

#### 5.5.2 The `LeaseRenewalEvent` Class

This class defines the event that is sent by the `LeaseRenewalManager` to an entity's registered listener when the `LeaseRenewalManager` fails to renew one of the leases it is managing for the entity. As previously stated, such failures typically occur because: the expiration time of the lease has been reached (and the lease has already expired) before the renewal request can be made; the renewal request has been denied by the lease grantor, even though the desired absolute expiration time of the lease has not yet been reached; or the renewal request could not be completed before the expiration of the lease. The `LeaseRenewalEvent` class encapsulates information about both the lease on which the failure occurred, as well as information about the condition that caused the renewal attempt to fail.

```
package net.jini.lease;  
  
public interface LeaseRenewalEvent extends EventObject  
{  
    public LeaseRenewalEvent(LeaseRenewalManager source,  
                             Lease lease,  
                             long expiration,  
                             Exception ex);  
  
    public Lease getLease();  
}
```

```
    public long getExpiration();  
    public Exception getException();  
}
```

The `LeaseRenewalEvent` class is a subclass of the class `EventObject`, adding the following additional items of abstract state: a reference to the affected `Lease` object; a long value representing the desired absolute expiration of the affected lease; and the exception (if any) that caused the event to be sent. In addition to the methods of the `EventObject` class, this class defines methods through which this additional state may be retrieved.

## The Semantics

The constructor of the `LeaseRenewalEvent` class takes the following parameters as input:

- ◆ A reference to the instance of the `LeaseRenewalManager` that generated the event
- ◆ The lease on which the renewal attempt failed, and to which the event pertains
- ◆ The desired (absolute) time of expiration of the affected lease
- ◆ An instance of the exception (if any) that caused the event to be sent

The `getLease` method returns a reference to the `Lease` object associated with the event. This method takes no arguments.

The `getExpiration` method returns a long value representing the desired absolute expiration of the `Lease` object associated with the event. This method takes no input arguments.

The `getException` method returns the exception that caused the event to be sent. This method takes no input arguments. The conditions under which a `LeaseRenewalEvent` may be sent, and the related values returned by this method, are as follows:

- ◆ If the lease's expiration time is reached before the `LeaseRenewalManager` can request renewal, a `LeaseRenewalEvent` will be sent with no associated exception. In this case, invoking this method will return `null`.
- ◆ If the `LeaseRenewalManager` sends a `LeaseRenewalEvent` because a renewal request was denied by the lease grantor even though the lease's expiration time has not yet been reached, this method will return a `LeaseDeniedException`.

- ◆ If the LeaseRenewalManager sends a LeaseRenewalEvent because a renewal request could not be completed before the expiration of the lease, this method will return an UnknownLeaseException.

Note that both LeaseDeniedException and UnknownLeaseException classes are defined in the *Jini™ Distributed Leasing Specification*.

---

# The JoinManager

## 6.1 Overview

A goal of any well-behaved Jini service, implemented within the bounds defined by the Jini technology programming model, is to advertise the service it provides by requesting residency within at least one Jini lookup service. Making such a request of a Jini lookup service is known as registering with, or *joining*, a lookup service. To demonstrate this good behavior, a service must comply with both the *multicast discovery protocol* and the *unicast discovery protocol* in order to discover the lookup services it is interested in joining. The service must also comply with the *join protocol* to register with the desired lookup services. The details of the discovery and join protocols are described in the *Jini™ Discovery and Join Specification*.

In order for the service to maintain its residency in the lookup services it has joined, the service must provide for the coordination, systematic renewal, and overall management of all leases on that residency. In addition to handling all discovery and join duties, as well as managing all leases on lookup residency, the service must provide for the coordination and management of any attribute sets with which it may have registered.

With respect to the duties described above, a Jini service may perform all but the attribute set management duties through the use of the `LookupDiscoveryManager` and `LeaseRenewalManager` helper utility classes (for information on these classes, refer to the chapters in this specification titled *The LookupDiscoveryManager* and *The LeaseRenewalManager*).

Rather than writing a service to use these classes in a coordinated fashion (in addition to providing for attribute management), the service may be written to employ the `JoinManager` class from the `net.jini.lookup` package. This utility class performs all of the functions related to discovery, joining, service lease renewal, and attribute management which the Jini technology programming model requires of a well-behaved Jini service. Each of these activities is inti-

mately involved with the maintenance of a service's residency in one or more lookup services (the service's *join state*), thus the name JoinManager.

The JoinManager class provides an implementation of the functionality described above. The use of this class in a wide variety of services can help minimize the work resulting from having to repeatedly implement this required functionality in each service.

The JoinManager is a utility class, not a remote service. Jini services that wish to use this utility will create an instance of the JoinManager in the service's address space to manage the entity's join state locally.

Note that when the term *service* is used, it refers to the object that has created an instance of the JoinManager and avails itself of the public methods of that utility class.

## 6.2 Other Types

The types defined in the specification of the JoinManager utility class are in the `net.jini.lookup` package. The following types may be referenced in this chapter. Whenever referenced, these object types will be referenced in unqualified form:

```
net.jini.core.lease.Lease
net.jini.core.entry.Entry
net.jini.core.lookup.ServiceID
net.jini.core.lookup.ServiceRegistrar
net.jini.core.lookup.ServiceRegistration
net.jini.discovery.DiscoveryListener
net.jini.discovery.DiscoveryManagement
net.jini.lookup.entry.ServiceControlled
net.jini.lease.LeaseRenewalManager
net.jini.discovery.LookupLocatorDiscovery
net.jini.discovery.LookupDiscoveryManager
java.io.IOException
java.rmi.MarshalledObject
java.util.EventListener
```

## 6.3 The Interface

The public methods provided by the JoinManager class are as follows:

```
package net.jini.lookup;

public class JoinManager
{
    public JoinManager(Object obj,
                       Entry[] attrSets,
                       ServiceIDListener callback,
                       DiscoveryManagement discoveryMgr,
                       LeaseRenewalManager leaseMgr)
                                   throws IOException;

    public JoinManager(Object obj,
                       Entry[] attrSets,
                       ServiceID serviceID,
                       DiscoveryManagement discoveryMgr,
                       LeaseRenewalManager leaseMgr)
                                   throws IOException;

    public DiscoveryManagement getDiscoveryManager();
    public LeaseRenewalManager getLeaseRenewalManager();
    public ServiceRegistrar[] getJoinSet();

    public Entry[] getAttributes();
    public void addAttributes(Entry[] attrSets);
    public void addAttributes(Entry[] attrSets,
                              boolean checkSC);
    public void setAttributes(Entry[] attrSets);
    public void modifyAttributes(Entry[] attrSetTemplates,
                                 Entry[] attrSets);
    public void modifyAttributes(Entry[] attrSetTemplates,
                                 Entry[] attrSets,
                                 boolean checkSC);

    public void terminate();
}
```

## 6.4 The Semantics

The `equals` method for this class returns `true` if and only if two instances of this class refer to the same object. That is, `x` and `y` are equal instances of this class if and only if `x == y` has the value `true`.

The individual semantics of each method of this class are described below.

- ◆ The constructor of the `JoinManager` class has two forms. Each form of the constructor throws `IOException` because construction of a `JoinManager` may initiate the multicast discovery process, which can throw `IOException`.

The first form of the constructor takes the following parameters as input:

- A reference to the service requesting the services of the `JoinManager`
- An array containing the service's attributes
- A reference to an object that implements the `ServiceIDListener` interface (belonging to the package `net.jini.lookup`)
- A reference to an object that implements the `DiscoveryManagement` interface
- An instance of the `LeaseRenewalManager` utility class

Passing `null` as the value of the `attrSets` parameter is equivalent to passing an empty `Entry` array.

The assignment of a service ID to the service will result in an event notification being sent to the listener object that was passed as the `ServiceIDListener` argument (`callback`). If a `null` value is passed in through this argument, then no such notification will be sent.

In order to use the `JoinManager`, the service supplies an object through which notifications that indicate a lookup service has been discovered or discarded will be received. At a minimum, this object must satisfy the contract defined in the `DiscoveryManagement` interface. That is, this object must provide the `JoinManager` with the ability to set discovery listeners and to discard previously discovered lookup services when they are found to be unavailable.

The `DiscoveryManagement` argument may be set to a value of `null`. If `null` is the value of this argument, then an instance of the `LookupDiscoveryManager` utility class will be constructed to listen for events announcing the discovery of only those lookup services that are members of the public group.

The `LeaseRenewalManager` argument may be set to a value of `null`. If `null` is the value of this argument, an instance of the `LeaseRenewalManager` class will be created, initially managing no `Lease` objects. This feature allows a service that employs the `JoinManager` to use either a single entity to manage all of its leases, or to use separate entities: one to manage the leases unrelated to the join process, and one to manage the leases that result from the join process and which are accessible only within the `JoinManager`.

The first form of the constructor is typically used by services that have not yet been assigned a service ID, but which have been pre-configured to join lookup services that the service identifies through the initialization of a discovery manager.

The second form of the constructor takes the same arguments as the first, except that an instance of the `ServiceID` replaces an instance of the `ServiceIDListener` interface. Note that the `ServiceID` class is defined in the *Jini™ Lookup Service Specification*, and the `ServiceIDListener` interface is described later in this document.

The second form of the constructor applies the same semantics to the `attrSets`, `discoveryMgr`, and `leaseMgr` arguments as is applied by the first form of the constructor.

The second form of the constructor should be used by services that have already been assigned a service ID (possibly by the service provider or as a result of a prior registration with some lookup service), and which may or may not have been pre-configured to join lookup services identified by group or by specific location.

- ◆ The `getDiscoveryManager` method returns the instance of `DiscoveryManagement` that was either passed into the constructor by the entity, or that was created as a result of `null` being input to that parameter. This method takes no arguments as input.

The object returned by this method encapsulates the mechanism by which either the `JoinManager` or the entity itself can set discovery listeners and discard previously discovered lookup services when they are found to be unavailable.

- ◆ The `getLeaseRenewalManager` method returns an instance of the `LeaseRenewalManager` class. This method takes no arguments as input.

The object returned by this method manages the leases requested and held by the `JoinManager`. Although it may also manage leases unrelated to the

join process that are requested and held by the service itself, the leases with which the JoinManager is concerned are the leases that correspond to the service registration requests the JoinManager has made with each lookup service the service wishes to join.

- ◆ The `getJoinSet` method returns an array of `ServiceRegistrar` objects, each corresponding to a lookup service with which the service is currently registered (joined). If there are no lookup services with which the service is currently registered, this method returns the empty array.

This method takes no arguments as input, and will return a new array upon each invocation.

- ◆ The `getAttributes` method returns an array containing the set of attributes currently associated with the service. If the service is not currently associated with an attribute set, this method returns the empty array.

This method takes no arguments as input, and will return a new array upon each invocation.

- ◆ The `addAttributes` method associates a new set of attributes with the service, in addition to the service's current set of attributes. The association of this new set of attributes with the service will be propagated to each lookup service with which the service is registered. This propagation must be performed asynchronously, so there is no guarantee that the propagation of the attributes to all lookup services with which the service is registered will have completed upon return from this method.

The set of attributes consisting of the union of the new set with the old set will be associated with the service in all future join processing.

There are two forms of the `addAttributes` method. Both forms of this method take as input an argument (`attrSets`) representing the set of attributes to associate with the service. This set is represented as an array of `Entry` objects, none of whose elements may be `null`. If at least one element of this input set is `null`, a `NullPointerException` is thrown.

An invocation of either form of this method with duplicate elements in the `attrSets` parameter (where duplication means attribute equality as defined by calling the `MarshaledObject.equals` method on field values) is equivalent to performing the invocation with the duplicates removed from that parameter. If `null` is passed in as the value of this parameter, a `NullPointerException` will be thrown.

The second form of this method also takes as input a flag indicating whether or not this method should determine if the attributes in the input set are instances of the `ServiceControlled` interface, which is a marker interface that is used to control which entities may modify a service's attribute set. For more information on this interface, refer to section 4.1 of the *Jini™ Lookup Attribute Schema Specification*. If the value of this flag is `true` and at least one of the attributes to be added is an instance of the `ServiceControlled` interface, a `SecurityException` will be thrown and propagated through this method.

Note that because there is no guarantee that attribute propagation will have completed upon return from this method, services that invoke this method must take care not to modify the contents of the input array. Doing so could cause the service's attribute state to be corrupted or inconsistent on a subset of the lookup services with which the service is registered as compared with the state reflected on the remaining lookup services. It is for this reason that the effects of modifying the contents of the input array, after this method is invoked, are undefined.

- ◆ The `setAttributes` method replaces the service's current set of attributes with the given new set of attributes. This method takes a single argument as input: an array of `Entry` objects, none of whose elements may be `null`, which represents the set of attributes that will replace the current set of attributes. If at least one element of this input set is `null`, a `NullPointerException` is thrown.

The replacement of the service's current set of attributes with the new set of attributes will be propagated to each lookup service with which the service is registered. This propagation must be performed asynchronously, so there is no guarantee that the propagation of the attributes to all lookup services with which the service is registered will have completed upon return from this method.

The service's new set of attributes will be associated with the service in all future join processing.

An invocation of this method with duplicate elements in the `attrSets` parameter (where duplication means attribute equality as defined by calling the `MarshaledObject.equals` method on field values) is equivalent to performing the invocation with the duplicates removed from that parameter. If `null` is input to `setAttributes`, a `NullPointerException` will be thrown.

For the same reason as noted above in the description of the `addAttributes` method, the effects of modifying the contents of the input array, after `setAttributes` is invoked, are undefined.

- ◆ The `modifyAttributes` method changes the service's current set of attributes using the same semantics as the `modifyAttributes` method of the `ServiceRegistration` class (see the *Jini™ Lookup Service Specification*). This method has two forms. The first form takes two arguments, the second form takes three arguments. Both forms will take an array of templates in the first argument, and an array of attributes in the second argument. The templates are used to identify which elements to modify from the service's current set of attributes. The attribute array contains the actual modifications to be made. The additional argument in the signature of the second form of `modifyAttributes` is a flag indicating whether or not this method should determine if the attributes in the input set are instances of the `ServiceControlled` interface, which is a marker interface used to control which entities may modify a service's attribute set (see section 4.1 of the *Jini™ Lookup Attribute Schema Specification*). If the value of this flag is true and at least one of the attributes to be modified is an instance of the `ServiceControlled` interface, a `SecurityException` will be thrown and propagated through this method.

The association of the new set of attributes with the service will be propagated to each lookup service with which the service is registered. This propagation must be performed asynchronously. Because of this asynchronous behavior, there is no guarantee that the propagation of the attributes to all lookup services with which the service is registered will have completed upon return from this method.

The set of attributes that results after the modifications have been applied will be associated with the service in all future join processing.

If the length of the array containing the templates does not equal the length of the array containing the attributes, an `IllegalArgumentException` will be thrown and propagated through this method.

For the same reason as that noted above in the description of the `addAttributes` method, the effects of modifying the contents of the `attrSets` parameter, after `modifyAttributes` is invoked, are undefined.

- ◆ The `terminate` method performs cleanup duties related to the termination of the *lookup service* discovery event mechanism, as well as to the lease and thread management performed by the `JoinManager`.

This method will cancel all of the service's managed leases that were granted by the lookup services with which the service is registered, and will terminate all threads that have been created.

If the discovery manager employed by the `JoinManager` was created by the `JoinManager` itself, this method will terminate *all* discovery processing being performed by that manager object on behalf of the service; otherwise, the discovery manager supplied by the service is still valid.

Whether an instance of the `LeaseRenewalManager` class was supplied by the service or created by the `JoinManager` itself, any reference to that object obtained by the service prior to termination will still be valid after termination.

The `JoinManager` makes certain concurrency guarantees with respect to an invocation of the `terminate` method while other method invocations are in progress. The termination process described above will not begin until completion of all invocations of the methods defined in the public interface of the `JoinManager`. Furthermore, once the termination process has begun, no remote method invocations will be made by the `JoinManager`, and all other method invocations on the `JoinManager` will not return until the termination process has completed. Upon completion of the termination process, the semantics of all current and future method invocations on the current instance of the `JoinManager` are undefined, although the reference to the `LeaseRenewalManager` object employed by the `JoinManager` is still valid.

## 6.5 Supporting Interfaces and Classes

The `JoinManager` utility class depends on the following interfaces: `DiscoveryManagement` and `ServiceIDListener` discussed below.

This class also references the following concrete classes: `LookupDiscoveryManager` and `LeaseRenewalManager`, each described in a separate chapter of this document.

### 6.5.1 The `DiscoveryManagement` Interface

Although it is not necessary for the `JoinManager` itself to execute the discovery process, it does need to be notified when one of the lookup services it wishes to join is discovered or discarded. Thus, at a minimum, the `JoinManager` requires access to the discovery events sent to the listeners registered with the discovery process' event mechanism. The instance of `DiscoveryManagement` that is passed

as an argument to the constructor of the JoinManager provides a mechanism for acquiring access to those events. For a complete description of the semantics of the methods of this interface, refer to the chapter of this specification titled *The Discovery Management Interfaces*.

One noteworthy item about the semantics of the JoinManager is the effect that invocations of the discard method of DiscoveryManagement will have on any discovery listeners created by the JoinManager. The DiscoveryManagement interface specifies that the discard method will remove a particular lookup service from the managed set of lookup services that have already been discovered, allowing that lookup service to be re-discovered. Invoking this method will result in the flushing of the lookup service from the appropriate cache, ultimately causing a discard notification to be sent to all DiscoveryListener objects registered with the event mechanism of the discovery process, including all listeners registered by the JoinManager.

The receipt of an event notification indicating that a lookup service has been discarded ultimately results in the removal (but not cancellation) of the registration lease that was granted by the discarded lookup service, and which is managed by the LeaseRenewalManager on behalf of the JoinManager. After removal occurs, the lease will eventually expire.

### 6.5.2 The ServiceIDListener Interface

The ServiceIDListener interface defines the methods used by a service to register a request for notification from the JoinManager upon the assignment of a serviceID by a lookup service. It is the responsibility of the service to create and pass into the JoinManager an object that implements this interface. That implementation must provide the definition of the actions to take upon receipt of the notification. Typically, the action taken will be to persist the assigned serviceID reference.

```
package net.jini.lookup;

public interface ServiceIDListener extends EventListener
{
    public void serviceIDNotify(ServiceID serviceID);
}
```

---

# The ClientLookupManager

## 7.1 Overview

The interactions of an entity that operates in a client-like fashion within a Jini application environment are generally distinguished by the fact that the entity first *discovers* one or more Jini lookup services, then *queries* one or more of the discovered lookup services for references to Jini services that the entity may employ in some task. Although one of the characteristics that distinguishes a Jini service from a Jini client is the service's ability to be registered with a Jini lookup service, both Jini services and clients can demonstrate the client-like characteristics just described. Thus, the interactions that occur between Jini lookup services and these so-called client-like entities include discovery processing as well as service queries (lookups).

Note that throughout this chapter one of two terms will be used interchangeably when referring to Jini clients and services that interact with a lookup service in such a client-like fashion, and which create an instance of the `ClientLookupManager` (from the package `net.jini.lookup`) and avail themselves of the public methods of that class. Those terms are: *entity* and *client-like entity*.

Once a client-like entity discovers a set of lookup services and retrieves references to desired services from those lookup services, the entity may choose to discontinue query-related discovery processing. That is, having obtained references to all of the services it wishes to employ, the entity may view the references it holds to the lookup services as no longer necessary.

But over the execution life of any such entity, partial failures such as system crashes or network outages may intermittently affect the availability of some of those services of interest. This results in a need to re-query the lookup services to find references to new instances of the service that can replace the unavailable instance. Such scenarios make it desirable for a client-like entity to maintain its references to the lookup services it queries. If an instance of a service is found to

be unavailable, the entity can query those lookup services to obtain an instance of the service which is available.

Since a query on a lookup service is a remote call, such calls are much more costly in terms of overhead and failure risk than are local calls. This cost is magnified when an entity must make frequent queries for multiple services, so an entity may find it desirable to cache the services it obtains from the original queries on the lookup services. Furthermore, by populating the cache with multiple instances of the desired services, redundancy in the availability of those services can be provided. Thus, if an instance of a service is found to be unavailable when needed, the entity can execute a local query on the cache rather than one or more remote queries on the lookup services to obtain an instance which is available.

Typically, an entity will request the creation of a separate cache for each service type of interest. The cache provides a method with which the entity can retrieve an element of the cache. In general, the particular service reference that is returned should not matter to the entity. It should only matter that *a* service reference has been returned, not *which* service reference. If for some reason it does matter to an entity which service reference is returned, then the cache also provides a mechanism which will allow the entity to retrieve all elements of the cache. The entity can then iterate through each element, selecting the particular reference it desires.

Although interacting with a local cache of services in this way can be very useful to entities that need frequent access to multiple services, some client-like entities may wish to interact with the cache in a reactive manner. For example, an entity such as a service browser typically wishes to be *notified* of the arrival of new services of interest as well as any changes in the state of the current services in the cache. Polling for such changes is usually viewed as undesirable. If the cache were to also provide an event mechanism with notification semantics, the needs of both types of entity could be satisfied.

From the scenarios discussed above, one could conclude that when acting in a client-like fashion, it is desirable for an entity to maintain, as much as possible, up-to-date knowledge of the availability of the *lookup* services of interest as well as the state information associated with all other types of services in which the entity is interested. By maintaining current service state information, the entity can implement efficient mechanisms for service access and usage.

The `ClientLookupManager` class is a helper utility class that any client-like entity can use to create and populate a cache such as that described previously, and with which the entity can register for notification of the availability of services of interest. Like the `JoinManager` utility class, this class needs to be notified when a desired lookup service is discovered. For information on the `JoinManager` utility class, refer to the chapter of this document titled *The JoinManager*.

Unlike the `JoinManager`, the `ClientLookupManager` does not register the entity as a service with discovered lookup services. Although both the `JoinManager` and the `ClientLookupManager` perform lookup discovery event handling for the entities that employ them, the `JoinManager` performs *join* processing for Jini services, while the `ClientLookupManager` performs *service discovery and management* processing both for clients and for services. Thus, typical usage patterns for Jini services wishing to find and use other Jini services generally indicate the employment of both the `JoinManager` and the `ClientLookupManager` utilities, whereas Jini clients would typically use only the `ClientLookupManager`.

The `ClientLookupManager` class can be asked to “discover” services an entity is interested in using, and to cache the references to those services as each is found. The cache can be viewed as a set of service references that the entity can access locally as needed through one of the public, non-remote methods provided in the cache’s interface. A service reference added to the cache will be removed from the cache when all of the lookup services with which that service is registered have been discarded.

The `ClientLookupManager` class also provides a mechanism for an entity to request that it be notified when a service of interest is discovered for the first time or has encountered a state change such as removal from all lookup services or attribute set changes.

For convenience, this class also provides versions of a method named `lookup`, which employs invocation semantics similar to the semantics of the `lookup` method of the `ServiceRegistrar` interface defined in the *Jini™ Lookup Service Specification*. This method may be useful to entities needing to find services on an infrequent basis, or when the cost of making a remote call is outweighed by the overhead of maintaining a local cache (for example, due to limited resources).

All three mechanisms described above—local queries on the cache, service discovery notification, and remote lookups—employ the same template-matching scheme as that described in the *Jini™ Lookup Service Specification*. Additionally, each mechanism allows the entity to supply an object referred to as a *filter*. Such an object is a non-remote object that defines additional matching criteria that the `ClientLookupManager` applies when searching for the entity’s services of interest. This filtering facility is particularly useful to entities that wish to extend the capabilities of the standard template-matching scheme.

The `ClientLookupManager` is a utility class, not a remote service. Client-like entities that wish to use this utility will create an instance of the `ClientLookupManager` in the entity’s address space so as to manage the entity’s “lookup state” locally.

## 7.2 The Object Types

The types defined in the specification of the ClientLookupManager utility class are in the `net.jini.lookup` package. The following types may be referenced in this chapter. Whenever referenced, these object types will be referenced in unqualified form:

```
net.jini.core.discovery.LookupLocator
net.jini.core.lease.Lease
net.jini.core.lookup.ServiceItem
net.jini.core.lookup.ServiceMatches
net.jini.core.lookup.ServiceRegistrar
net.jini.core.lookup.ServiceTemplate
net.jini.discovery.DiscoveryListener
net.jini.discovery.DiscoveryManagement
net.jini.discovery.LookupDiscoveryManager
net.jini.event.ServiceDiscoveryEvent
net.jini.lease.LeaseRenewalManager
net.jini.lookup.LookupCache
net.jini.lookup.ServiceDiscoveryListener
net.jini.lookup.ServiceItemFilter
java.io.IOException
java.rmi.server.UnicastRemoteObject
java.rmi.MarshalledObject
java.rmi.RemoteException
java.util.EventListener
java.util.EventObject
java.util.Set
```

## 7.3 The Interface

The public interface provided by the ClientLookupManager class defines methods that allow an entity to request that references to services matching criteria defined by the entity be found in discovered lookup services and cached for local retrieval. This interface also defines methods for retrieving the manager objects employed by this utility, and for performing termination processing.

```
package net.jini.lookup;

public class ClientLookupManager
{
```

```

    public ClientLookupManager
        (DiscoveryManagement discoveryMgr,
         LeaseRenewalManager leaseMgr)
        throws IOException;

    public LookupCache createLookupCache
        (ServiceTemplate template,
         ServiceItemFilter filter,
         ServiceDiscoveryListener listener)
        throws RemoteException;

    public ServiceItem lookup(ServiceTemplate tmpl,
                             ServiceItemFilter filter);

    public ServiceItem lookup(ServiceTemplate tmpl,
                             ServiceItemFilter filter,
                             long waitDur)
        throws InterruptedException,
            RemoteException;

    public ServiceItem[] lookup(ServiceTemplate tmpl,
                                int maxMatches,
                                ServiceItemFilter filter);

    public ServiceItem[] lookup(ServiceTemplate tmpl,
                                int minMatches,
                                int maxMatches,
                                ServiceItemFilter filter,
                                long waitDur)
        throws InterruptedException,
            RemoteException;

    public DiscoveryManagement getDiscoveryManager();
    public LeaseRenewalManager getLeaseRenewalManager();
    public void terminate();
}

```

## 7.4 The Semantics

The `ClientLookupManager` makes certain concurrency guarantees with respect to the methods it defines. When a method of the `ClientLookupManager` invokes a remote method, although such an invocation may block other remote calls made in the `ClientLookupManager`, invocations of local methods will not be blocked.

The `equals` method for this class returns `true` if and only if two instances of this class refer to the same object. That is, `x` and `y` are equal instances of this class if and only if `x == y` has the value `true`.

### 7.4.1 Exporting *RemoteEventListener* Objects

A subset of the methods on the *ClientLookupManager*, when invoked, will result in a request for registration with the event mechanism of one or more lookup services. The methods that result in such a request are *createLookupCache* and the so-called *blocking* versions of the *lookup* method, each described in this section.

Any entity that invokes one of these methods must export to each lookup service with which a registration occurs, the stub classes of the *RemoteEventListener* object through which instances of *RemoteEvent* will be received. Furthermore, each of these methods must throw *RemoteException*. The reasons that a *RemoteException* can occur fall into one of the following categories:

- ◆ Each of these methods attempts to export a remote object, a process that can throw *RemoteException*.
- ◆ Each of these methods attempts to register with the event mechanism of at least one lookup service, a process that can throw *RemoteException*.

How this set of *ClientLookupManager* methods handles the *RemoteException* is dependent on the reason for the exception. If a *RemoteException* (or any other non-fatal exception or error) is thrown during an attempt to register for events from a lookup service, that lookup service will be discarded and made eligible for re-discovery. On the other hand, if the *RemoteException* is thrown during an attempt to export the listener, the method will exit and the exception will be propagated.

The potential for *RemoteException* during the export process imposes the following requirement: the *same* instance of the listener must be exported to each lookup service from which events will be requested. Furthermore, the creation and export of the listener must occur prior to the event registration process. This requirement guarantees that should a *RemoteException* occur after the registration process has begun, the exception will not be propagated and event processing will continue.

To understand the significance of this requirement, consider the scenario where a different instance of the listener is exported to each lookup service. If a new lookup service is discovered after the event process has begun for the other lookup services in the managed set, a new instance of the listener must be created and exported. Should a *RemoteException* occur during the export process, the exception will be propagated and all event processing will stop—a result that many entities may view as undesirable.

In order to facilitate exporting the listener, the entity—whether it is a Jini client or a Jini service—is responsible for providing and advertising a mechanism through which each lookup service will acquire the listener’s stub classes.

For example, one implementation of the `ClientLookupManager` might provide a special JAR file containing only the listener stub classes (to optimize download time). By including this JAR file in the entity’s `java.rmi.server.codebase` property (in the appropriate format specifying transport protocol and location), the entity *advertises* the mechanism that lookup services can employ to acquire the stub classes. By executing a process to serve up the JAR file (for example, an HTTP server), the mechanism through which each lookup service acquires those stub classes is *provided*.

It is important to note that should such a mechanism not be made available to each lookup service with which event registration will be requested, a “silent failure” can occur repeatedly. If the mechanism is not available, each lookup service cannot acquire the exported listener. Because each lookup service cannot acquire the exported listener, any attempts to register for events will fail. Whenever an attempt to register for events fails, the associated lookup service will be discarded and made eligible for re-discovery. Upon re-discovery of the discarded lookup service, the cycle repeats when a new attempt to register for events is made.

The individual semantics of each method of this class are described here:

- ◆ The constructor of the `ClientLookupManager` takes two arguments: an object that implements the `DiscoveryManagement` interface and a reference to a `LeaseRenewalManager` object. The constructor throws an `IOException` because construction of a `ClientLookupManager` may initiate the multicast discovery process, a process that can throw `IOException`.

In order to use the `ClientLookupManager`, an entity supplies an object through which notifications that indicate a lookup service has been discovered or discarded will be received. At a minimum, this object must satisfy the contract defined in the `DiscoveryManagement` interface. That is, this object must provide the `ClientLookupManager` with the ability to set discovery listeners and to discard previously discovered lookup services when they are found to be unavailable.

A value of `null` may be passed as the `DiscoveryManagement` argument. If the value of the argument is `null`, then an instance of the `LookupDiscoveryManager` utility class will be constructed to listen for events announcing the discovery of only those lookup services that are members of the public group.

A value of `null` may be passed as the `LeaseRenewalManager` argument. If the value of the argument is `null`, an instance of the `LeaseRenewalManager` class will be created, initially managing no `Lease` objects.

- ◆ The `createLookupCache` method allows the client-like entity to request that the `ClientLookupManager` create a new managed set (or cache) and populate it with services, which match criteria defined by the entity, and whose references are registered with one or more of the lookup services the entity has targeted for discovery.

This method returns an object of type `LookupCache`. Through this return value, the entity can query the cache for services of interest, manage the cache's event mechanism for service discoveries, or terminate the cache. The specification of the `LookupCache` interface is presented later in this chapter.

An entity typically uses the object returned by this method to provide *local* storage of, and access to, references to services that it is interested in using. Entities needing frequent access to numerous services will find the object returned by this method quite useful because acquisition of those service references is provided through local method invocations. Additionally, because the object returned by this method provides an event mechanism, it is also useful to entities wishing to simply monitor, in an event-driven manner, the state changes that occur in the services of interest.

The `createLookupCache` method takes three arguments: an instance of `ServiceTemplate`, an instance of `ServiceItemFilter`, and an instance of `ServiceDiscoveryListener`. Both the `ServiceItemFilter` and `ServiceDiscoveryListener` interfaces are presented later in this chapter.

Together, the template and the filter arguments define the criteria with which service-matching should be performed. The listener argument references an object that will receive notifications when services matching the input criteria are discovered for the first time, or have encountered a state change such as removal from all lookup services or attribute set changes. If `null` is input to the listener argument for a particular invocation of this method, the cache resulting from that invocation will send no such notifications.

The template argument employs template-matching semantics identical to the semantics described in the *Jini™ Lookup Service Specification* (where the `ServiceTemplate` interface is defined) to identify the service(s) to acquire from lookup services in the managed set. The object passed to the filter argument is then used to apply additional matching criteria to any

service references found through template-matching. The additional matching criteria defined by the `filter` parameter are application-specific, and therefore, must be defined by the client-like entity itself (as described in the section titled *The ServiceItemFilter Interface*). Furthermore, once an instance of the cache is created, any filter associated with that instance will not change during the life of that particular cache.

As a convenience, a `null` reference input to the template argument is treated as equivalent to inputting a `ServiceTemplate` constructed with all `null` arguments (all *wildcards*). That is, the cache will attempt to discover all services contained in each lookup service in the managed set. If a `null` value is passed as the filter argument, then only template-matching will be employed to find the desired services.

Entities that invoke this method must take care not to modify the contents of the input template after the cache has been created. Doing so could cause the state of the cache to become corrupted or inconsistent. It is for this reason that the effects of modifying the contents of the input template, after this method is invoked, are undefined.

## Events and the Cache

In order to keep its contents up-to-date, the cache must register with the event mechanism of each lookup service in the managed set. From the point of view of the cache, a service is “discovered” when it receives a remote event from one of those lookup services notifying the cache of the existence of a service matching the input criteria. In addition, whenever one of the cache’s discovered services experiences a state change in one of the lookup services in which it is registered, the cache will receive a remote event identifying that state change whenever the change satisfies the matching criteria.

For a number of reasons the cache may receive multiple events corresponding to the same Jini service. For example, a particular Jini service may be registered with more than one lookup service from the managed set. Also, multiple configurations of the service may be registered with one or more of those lookup services. If the cache requests events from each lookup service using a template configured with no restriction along the service ID search axis and little or no restriction along the attribute search axis, the cache will receive a notification each time one of the following events occurs:

- ◆ Some configuration of the service, matching the template, is registered with one of the lookup services.

- ◆ The lease of one of the service references matching the template is cancelled or expires.
- ◆ An attribute set associated with one of the service references matching the template is modified in some way.

Just as the cache requests that it be notified of state changes in matching services occurring within each lookup service, an entity may request that the cache deliver events that indicate analogous state changes in the service references stored in the cache.

There are two significant differences in the event mechanism between the lookup services and the cache, and the event mechanism between the cache and the client-like entity. First and foremost, the events sent from the lookup services to the cache are *remote* events, whereas the events sent from the cache to the entity are *local* events. Secondly, each registration or state-change event sent from the cache to the entity may actually have been a result of multiple corresponding events received by the cache from a set of lookup services. Thus, there is a “many-to-one” relationship between the events received by the cache and the events sent by the cache.

For many entities that use the cache’s event mechanism to interact with the cache’s discovered services, knowledge of the number of distinct service references, as well as identification of the lookup services with which those references are registered, is of no interest. Such entities typically are interested only in acquiring *a* reference—not *all* references—to the desired services. Thus, the relationship between the two event mechanisms described previously allows the *ClientLookupManager* to hide the lookup services with which the cache interacts from the entity. For entities that are interested in the additional information, the cache provides methods separate from the event mechanism for obtaining such information.

To summarize, although the cache may receive *multiple* events signaling a state change related to a particular matching service, the cache will typically send only a *single* corresponding event to the entity. That is, for any matching service:

- ◆ The cache will send a *service discovery event* to the entity only once: after the cache acquires the *first* reference to the matching service.
- ◆ The cache will send a *service removal event* to the entity only once: after every reference to the service has had its lease expire or cancelled; that is, only after all references to the matching service have been removed from every lookup service in the cache’s managed set.
- ◆ For each set of event(s) notifying the cache that a particular modification has been made to the attribute set associated with one of the service references, one *service modification event* will be sent to the entity; but *only if* the

attribute set state reflected in the received event represents an actual change in the service's current attribute set state (as maintained by the cache).

With respect to the state of the attribute sets associated with the service references stored in the cache, the cache should be viewed as maintaining a single attribute set state for each collection of service references that represent the same service. That single state will always be equivalent to the state reflected in the last attribute set modification event received by the cache.

For example, suppose three different references to a service which matches the input criteria are each registered with three lookup services in the managed set. Suppose the attribute sets associated with each service reference are modified in exactly the same way. For this specific case, the cache would receive three events—one from each lookup service—signaling these modifications. Upon receipt of the first event, the cache modifies its current notion of the service's attribute set state, and then notifies the entity of the change; but only if the state reflected in the event represents a change in the current state. Because the remaining two events received by the cache represent the same state change as that represented in the first event, the cache sends no other notification.

Next, suppose a second modification, different from the first, is made on only two of the service references, and a third unique modification is made on the remaining service reference. In this case, the cache will still receive three events, but how the cache handles the events is dependent on the order of arrival of the events. For simplicity, call the three events  $e_1$ ,  $e_2$ , and  $e_3$ . Use  $s$  to represent the cache's current notion of the service's attribute set state, and use  $s_1$  and  $s_2$  to represent the states resulting after each attribute modification has occurred. In this example,  $e_1$  and  $e_2$  will be sent to the cache after the service's attribute sets are each modified to  $s_1$  in their respective lookup services. Event  $e_3$  is sent after the service's attribute sets are modified to  $s_2$  in the remaining lookup service.

If the order of arrival is  $e_1$ ,  $e_2$ , and then  $e_3$ , the cache will change  $s$  into  $s_1$  and notify the entity after the arrival of  $e_1$ , but will do nothing upon the arrival of  $e_2$ . Upon the arrival of  $e_3$ , the cache will change  $s$  (which is now  $s_1$ ) into  $s_2$ . If the order of arrival of the events is  $e_1$ ,  $e_3$ , and then  $e_2$ , the cache will first change  $s$  into  $s_1$ , then into  $s_2$ , and then back into  $s_1$  again. Furthermore, for each state change made, the cache will send a notification to the entity.

Thus, the events generated by the cache's event mechanism and sent by the cache to the entity are more representative of the state changes that occur in the cache than in the lookup services.

An entity may register for events from the cache in one of two ways. The entity may supply an instance of `ServiceDiscoveryListener` to the listener argument of the `createLookupCache` method, or it may invoke a method on the

cache to add a listener to the cache. Thus, an entity may register for events from the cache at any time during the execution life of the cache.

Similarly, the cache provides a method that an entity, which is currently registered for events from the cache, may use at any time to un-register with the cache's event mechanism.

- ◆ The `lookup` method queries each available lookup service in the managed set for service reference(s) that match criteria defined by the entity that invokes this method. Entities typically employ this method when they need infrequent access to services, and when the cost of making remote queries is outweighed by the overhead of maintaining a local cache (for example, because of resource limitations).

Although the `lookup` method has four versions, each version falls into one of two categories: those versions of this method that return a single instance of `ServiceItem`, and those versions that return a set of service references as an array of `ServiceItem` objects.

Two arguments are common to all versions of this method: an instance of `ServiceTemplate` and an instance of `ServiceItemFilter`.

The difference between the two versions of `lookup` in each of the two categories differ only in whether or not a particular version provides what is referred to as a “wait” (or blocking) feature. That is, within each category, one version of `lookup` will return immediately upon failure (or success), whereas the blocking version will declare failure only after waiting (and failing) a specified amount of time. The particular version of this method that an entity employs is typically determined by the entity's intended usage pattern.

The descriptions here refer to all versions of this method, except where explicitly noted.

The `template` argument and the `filter` argument both have semantics identical to that defined for these arguments in the description of the `createLookupCache` method above. In particular,

- ◆ A `null` reference value for the `template` argument is treated as the equivalent of a “wildcarded” `ServiceTemplate`.
- ◆ If `null` is the value for the `filter` argument, then only template-matching will be employed to find the desired services.
- ◆ The effects of modifying the contents of the `template` while the invocation is in progress are unpredictable and undefined.

If no service can be found that matches the desired criteria, then the versions of `lookup` from the first category—those that return a single instance of `ServiceItem`—will return `null`; whereas the versions from the second category—those that return an array of `ServiceItem` instances—will return an empty array.

The versions of this method from the first category can be used in a fashion similar to the first form of the `lookup` method defined in the `ServiceRegistrar` interface described in the *Jini™ Lookup Service Specification*. That is, an entity would typically invoke one of these versions of `lookup` when it wishes to find a *single* service reference, and the particular lookup service with which that service reference is registered is unimportant to the entity.

These versions of `lookup` differ with the corresponding version of `lookup` in `ServiceRegistrar` in the following ways:

- ◆ These versions of `lookup` query *multiple* lookup services (the order in which the lookup services are queried is defined by the implementation).
- ◆ These versions of `lookup` can apply additional matching criteria, in the form of a filter object, when deciding whether a service reference found through standard template-matching should be returned to the entity.

The two versions of this method that return an array of `ServiceItem` objects can be used in a fashion similar to the second form of `lookup` defined in the `ServiceRegistrar` interface. That is, an entity would typically invoke these versions of `lookup` when it wishes to find *multiple* service references matching the input criteria. Each of the versions of `lookup` that return an array of `ServiceItem` objects takes as one of its arguments an `int` parameter, `maxMatches`, that represents the maximum number of matches that should be returned. The array returned by these methods will contain no more than `maxMatches` service references, although it may contain fewer than that number.

As with the versions of `lookup` that return a single instance of `ServiceItem`, multiple queries and filtering are also notable differences between the second-category versions of this method and their counterpart in `ServiceRegistrar`.

For all of the versions of `lookup`, whenever a lookup service query returns a `null` service reference, the filter will be by-passed. On the other hand, whenever a lookup service query returns a non-`null` service reference in which one or more elements of the associated attribute sets array is `null`, the

filter will be applied, but with the `null` elements of the attribute sets array removed. Upon finding a successful match, the service item will be returned in the appropriate way, with the `null` elements of the attribute sets array removed.

Each version of `lookup` may be confronted with *duplicate* references during a search for a service of interest. This is because the same service may register with more than one lookup service in the managed set. As with the cache, when a set of service references is returned by `lookup`, each service reference in the return set will be unique with respect to all other service references in the set; as determined by the `equals` method provided by each reference.

If it is determined that a lookup service is unavailable (due to an exception or some other non-fatal error) while interacting with a lookup service from the managed set, all versions of `lookup` will invoke the `discard` method on the instance of `DiscoveryManagement` being employed by the `ClientLookupManager`. Doing so will result in the unavailable lookup service being discarded and made eligible for re-discovery.

Recall that the propagation of modifications to a service's attributes across a set of lookup services typically occurs asynchronously. It is for this reason that while invoking `lookup` to find a set of matching services, it is possible that the set returned may reflect multiple references having the same service ID with different attributes. Note that although this sort of inconsistent state can also occur if the entity employs a cache, the cache will eventually reflect the correct state.

### The Blocking Feature of Lookup

As noted above, each category contains a version of `lookup` that provides a feature in which the entity can request that if the number of service references found throughout the available lookup services does not fall into a desired range, the method will wait a finite period of time until either an acceptable minimum number of service references are discovered, or the specified time period has passed.

The versions of `lookup` providing this blocking feature each takes as one of its parameters a value of type `long` that represents the number of milliseconds to wait for the service to be discovered. In addition to `RemoteException` (described previously for these methods), each of these versions of `lookup` may throw an `InterruptedException`.

One of these blocking versions of `lookup` implicitly uses a value of one for both the acceptable minimum and the allowable maximum number of service ref-

erences to discover. The other blocking version requires that the entity specify the range through the `minMatches` and `maxMatches` parameters respectively.

Prior to blocking, each of these versions of `lookup` first queries each available lookup service in an attempt to retrieve a satisfactory number of matching services. Whether or not the method actually blocks is dependent on how many matching service references are found during the query process. Blocking occurs only if after querying *all* of the available lookup services, the number of matching services found is less than the acceptable minimum. If the waiting period passes before that minimum number of service references is found, the method will return the service references that have been discovered up to that point. If the waiting period passes and no services have been found, `null` or an empty array (depending on the version of `lookup`) will be returned.

If after querying all of the available lookup services the number of matching services found is greater than or equal to the specified minimum, but less than the specified maximum, the method will return the currently discovered service references without blocking. If the initial query process produces the desired maximum number of service references, the method will return the results immediately.

The blocking versions of `lookup` are quite useful to entities that cannot proceed until such a service of interest is found. If a non-positive value is input to the `waitDur` argument, then the method will not wait. It will simply query the available lookup services and employ the return semantics described above.

The values of the `minMatches` and `maxMatches` arguments must both be positive, and `maxMatches` must be greater than or equal to `minMatches`; otherwise, an `IllegalArgumentException` will be thrown.

The blocking versions of `lookup` make a concurrency guarantee with respect to the discovery of new lookup services during the wait period. That is, while waiting for matching service reference(s) to be discovered, if one or more of the desired—but previously unavailable—lookup services is discovered and added to the managed set, those new lookup services will also be queried for the service(s) of interest.

Additionally, both blocking versions of `lookup` throw an `InterruptedException`. When an entity invokes either version with valid parameters, the entity may decide during the wait period that it no longer wishes to wait the entire period for the method to return. Thus, while the method is blocking on the discovery of matching service(s), it may be interrupted by invoking the `interrupt` method from the `Thread` class. The intent of this mechanism is to allow the entity to interrupt a blocking `lookup` in the same way it would a sleeping thread.

- ◆ The `getDiscoveryManager` method will return an object that implements the `DiscoveryManagement` interface. The object returned by this method provides the `ClientLookupManager` with the ability to set discovery listeners and to discard previously discovered lookup services when they are found to be unavailable. This method takes no arguments.
- ◆ The `getLeaseRenewalManager` method will return an instance of the `LeaseRenewalManager` class. The object returned by this method manages the leases requested and held by the `ClientLookupManager`. In general, these leases correspond to the registrations made by the `ClientLookupManager` with the event mechanism of each lookup service in the managed set. This method takes no arguments.
- ◆ The `terminate` method performs cleanup duties related to the termination of the event mechanism for *lookup service* discovery, the event mechanism for *service* discovery, and the cache management duties of the `ClientLookupManager`.

For each instance of `LookupCache` created and managed by the `ClientLookupManager`, the `terminate` method will do the following:

- Either remove all listener objects registered for receipt of `DiscoveryEvent` objects or, if the discovery manager employed by the `ClientLookupManager` was created by the `ClientLookupManager` itself, terminate *all* discovery processing being performed by that manager object on behalf of the entity.
- Cancel all event leases granted by each lookup service in the managed set of lookup services.
- Un-export all remote listener objects registered with each lookup service in the managed set.
- Terminate all threads involved in the process of retrieving and storing references to discovered services of interest.

Note that if the service obtains references to the discovery manager (as long as it wasn't created by the `ClientLookupManager` itself) and the lease renewal manager prior to termination, those references will still be valid after termination.

The `ClientLookupManager` makes certain concurrency guarantees with respect to an invocation of the `terminate` method while other method invocations are in progress. The termination process described above will not begin until completion of all invocations of the methods defined in the public interface of the `ClientLookupManager`; that is, until completion of

invocations of `createLookupCache`, `lookup`, `getDiscoveryManager`, and `getLeaseRenewalManager`.

Additionally, once the termination process has begun, no remote method invocations will be made by the `ClientLookupManager`, and all other method invocations on the `ClientLookupManager` will not return until the termination process has completed. Upon completion of the termination process, the semantics of all current and future method invocations on the current instance of the `ClientLookupManager` are undefined.

## 7.5 Supporting Interfaces and Classes

The `ClientLookupManager` utility class depends on the following interfaces defined in the *Jini™ Lookup Service Specification*: `ServiceTemplate`, `ServiceItem`, and `ServiceMatches`. This class also depends on a number of interfaces, each defined in this section; those interfaces are: `DiscoveryManagement`, `ServiceItemFilter`, `ServiceDiscoveryListener`, and `LookupCache`.

The `ClientLookupManager` class references the following concrete classes: `LookupDiscoveryManager` and `LeaseRenewalManager`, each described in a separate chapter of this document, and `ServiceDiscoveryEvent` defined in this chapter.

### 7.5.1 The DiscoveryManagement Interface

Although it is not necessary for the `ClientLookupManager` itself to execute the discovery process, it does need to be notified when one of the lookup services it wishes to query is discovered or discarded. Thus, at a minimum, the `ClientLookupManager` requires access to the instances of `DiscoveryEvent` sent to the listeners registered with the event mechanism of the discovery process. The instance of `DiscoveryManagement` passed to the constructor of the `ClientLookupManager` provides a mechanism for acquiring access to those events. For a complete description of the semantics of the methods of this interface, refer to the chapter of this specification titled *The Discovery Management Interfaces*.

One noteworthy item about the semantics of the `ClientLookupManager` is the effect that invocations of the `discard` method of `DiscoveryManagement` have on any cache objects created by the `ClientLookupManager`. The `DiscoveryManagement` interface specifies that the `discard` method will remove a particular lookup service from the managed set of lookup services that have

already been discovered, allowing that lookup service to be re-discovered. Invoking this method will result in the flushing of the lookup service from the appropriate cache. This effect ultimately causes a discard notification to be sent to all *DiscoveryListener* objects registered with the event mechanism of the discovery process (including all listeners registered by the *ClientLookupManager*).

The receipt of an event notification indicating that a lookup service from the managed set has been discarded must ultimately result in the cancellation and removal of all event leases that were granted by the discarded lookup service, and that are managed by the *LeaseRenewalManager* on behalf of the *ClientLookupManager*.

Furthermore, every service reference stored in the cache that is registered with the discarded lookup service but is not registered with any of the remaining lookup services in the managed set, will be “discarded” as well. That is, all previously discovered service references that are registered with only unavailable lookup services, will be removed from the cache and made eligible for service re-discovery.

### 7.5.2 The *ServiceItemFilter* Interface

The *ServiceItemFilter* interface defines the methods used by an object such as the *ClientLookupManager* or the *LookupCache* to apply additional matching criteria when searching for services in which an entity has registered interest. It is the responsibility of the entity requesting the application of additional criteria to construct an implementation of this interface that defines the additional criteria, and to pass the resulting object (referred to as a *filter*) into the object that will apply it.

The filtering mechanism provided by implementations of this interface is particularly useful to entities that wish to extend the capabilities of the standard template matching scheme. For example, because template matching does not allow one to search for services based on a range of attribute values, this additional matching mechanism can be exploited by the entity to ask the managing object to find all registered printer services that have a resolution attribute *between* say, 300 dpi and 1200 dpi.

```
package net.jini.lookup;

public interface ServiceItemFilter
{
    public boolean check(ServiceItem item);
}
```

```
    public ServiceItem getPreEventServiceItem();  
    public ServiceItem getPostEventServiceItem();  
}
```

## The Semantics

The constructor of `ServiceDiscoveryEvent` takes three arguments:

- ◆ An instance of `Object` corresponding to the instance of `LookupCache` from which the given event originated
- ◆ A `ServiceItem` reference representing the state of the service (associated with the given event) *prior* to the occurrence of the event
- ◆ A `ServiceItem` reference representing the state of the service *after* the occurrence of the event

If `null` is passed as the `source` parameter for the constructor, a `NullPointerException` will be thrown.

Depending on the nature of the discovery event, a `null` reference may be passed as one or the other of the remaining parameters, but never both. If `null` is passed as both the `preEventItem` and the `postEventItem` parameters, a `NullPointerException` will be thrown.

Note that the constructor will not modify the contents of either `ServiceItem` argument. Doing so can result in unpredictable and undesirable effects on future processing by the `ClientLookupManager`. That is why the effects of any such modification to the contents of either input parameter are undefined.

The `getPreEventServiceItem` method returns an instance of `ServiceItem` containing the service reference corresponding to the given event. The service state reflected in the returned service item is the state of the service *prior* to the occurrence of the event.

If the event is a discovery event (as opposed to a removal or modification event), then this method will return `null` because the discovered service had no state in the cache prior to its discovery.

The `getPostEventServiceItem` method returns an instance of `ServiceItem` containing the service reference corresponding to the given event. The service state reflected in the returned service item is the state of the service *after* the occurrence of the event.

If the event is a removal event, then this method will return `null` because the discovered service has no state in the cache after it is removed from the cache.

Because making a copy can be a very expensive process, neither accessor method returns a copy of the service reference associated with the given event. Rather, each method returns the appropriate service reference from the cache itself. Due to this cost, listeners (see `ServiceDiscoveryListener`, next) that receive a `ServiceDiscoveryEvent` must not modify the contents of the object returned by these methods; doing so could cause the state of the cache to become corrupted or inconsistent because the objects returned by these methods are also members of the cache. This potential for corruption or inconsistency is why the effects of modifying the object returned by either accessor method are undefined.

#### 7.5.4 The `ServiceDiscoveryListener` Interface

The `ServiceDiscoveryListener` interface defines the methods used by objects such as a `LookupCache` to notify an entity that events of interest related to the elements of the cache have occurred. It is the responsibility of the entity wishing to be notified of the occurrence of such events to construct an object that implements the `ServiceDiscoveryListener` interface and then register that object with the cache's event mechanism. Any implementation of this interface must define the actions to take upon receipt of an event notification. The action taken is dependent on both the application and the particular event that has occurred.

```
package net.jini.lookup;

public interface ServiceDiscoveryListener
{
    public void serviceAdded(ServiceDiscoveryEvent event);
    public void serviceRemoved(ServiceDiscoveryEvent event);
    public void serviceChanged(ServiceDiscoveryEvent event);
}
```

#### The Semantics

As described previously in the section titled *Events and the Cache*: when the cache receives from one of the managed lookup services, an event signaling the *registration* of a service of interest for the *first time* (or for the first time since the service has been discarded), the cache invokes the `serviceAdded` method on all instances of `ServiceDiscoveryListener` that are registered with the cache; doing so notifies the entity that a service of interest has been discovered. The `serviceAdded` method takes one argument: an instance of `ServiceDiscoveryEvent` containing references to the service item corresponding to the event, including representations of the service's state both before and after the event.

When the cache receives, from a managed lookup service, an event signaling the *removal* of a service of interest from the *last* such lookup service with which it was registered, the cache invokes the `serviceRemoved` method on all instances of `ServiceDiscoveryListener` that are registered with the cache; doing so notifies the entity that a service of interest has been discarded. The `serviceRemoved` method takes one argument: a `ServiceDiscoveryEvent` object containing references to the service item corresponding to the event, including representations of the service's state both before and after the event.

When the cache receives, from a managed lookup service, an event signaling the unique *modification* of the attributes of a service of interest (across the attribute sets of all references to the service), the cache invokes the `serviceChanged` method on all instances of `ServiceDiscoveryListener` that are registered with the cache; doing so notifies the entity that the state of a service of interest has changed. The `serviceChanged` method takes one argument: a `ServiceDiscoveryEvent` object containing references to the service item corresponding to the event, including representations of the service's state both before and after the event.

Should an exception occur during an invocation of any of the methods defined by this interface, the semantics of how that exception is handled are undefined.

Each method defined by this interface must not modify the contents of the `ServiceDiscoveryEvent` parameter; doing so can result in unpredictable and undesirable effects on future processing by the `ClientLookupManager`. It is for this reason that if one of these methods modifies the contents of the parameter, the effects are undefined.

This interface makes the following concurrency guarantee. For any given listener object that implements this interface, no two methods (either the same two methods or different methods) defined by the interface can be invoked at the same time by the same cache. For example, the `serviceRemoved` method must not be invoked while the invocation of another listener's `serviceAdded` method is in progress.

Finally, it should be noted that the intent of the methods of this interface is to allow the recipient of the `ServiceDiscoveryEvent` to be informed that a service has been added to, removed from, or modified in the cache. Calls to these methods are synchronous to allow the entity that makes the call (for example, a thread that interacts with the various lookup services of interest) to determine whether or not the call succeeded. However, it is not part of the semantics of the call that the notification return can be delayed while the recipient of the call reacts to the occurrence of the event. Thus, it is highly recommended that implementations of this interface avoid time consuming operations, and return from the method as quickly as possible. For example, one strategy might be to simply note the occurrence of

the `ServiceDiscoveryEvent`, and perform any time consuming event handling asynchronously.

### 7.5.5 The LookupCache Interface

The `LookupCache` interface defines the methods provided by the object created and returned by the `ClientLookupManager` when a client-like entity invokes the `createLookupCache` method. It is within that object that discovered service references, which match criteria defined by the entity, are stored. Through this interface the entity may retrieve one or more of the stored service references, register and un-register with the cache's event mechanism, and terminate all of the cache's processing.

```
package net.jini.lookup;

public interface LookupCache
{
    public ServiceItem    lookup(ServiceItemFilter filter);
    public ServiceItem[] lookup(ServiceItemFilter filter,
                               int maxMatches);

    public void addListener
                  (ServiceDiscoveryListener listener);
    public void removeListener
                  (ServiceDiscoveryListener listener);

    public void discard(Object serviceReference);
    public void terminate();
}
```

### The Semantics

Depending on which version is invoked, the `lookup` method of the `LookupCache` interface returns one or more elements — each matching the input criteria — that were stored in the associated cache. The object returned is either a single instance of `ServiceItem`, or a set of service references in the form of an array of `ServiceItem` objects. Each service item returned by either form of this method must have been previously discovered to be both registered with one or more of the lookup services in the managed set, and to match criteria defined by the entity.

One argument is common to both forms of `lookup`: an instance of `ServiceItemFilter`. The semantics of the filter argument are identical to

those of the `filter` argument specified for a number of the methods defined in the interface of the `ClientLookupManager` utility class. This argument is intended to allow an entity to separate its filtering into two steps: an initial filter applied during the discovery phase, and then a finer resolution filter applied upon retrieval from the cache. As with the methods of the `ClientLookupManager`, if `null` is the value of this argument, then no additional filtering will be performed.

The second form of the `lookup` method of the `LookupCache` interface takes an additional argument: a parameter of type `int` that represents the maximum number of matches that should be returned. The array returned by this form of `lookup` will contain no more than the requested number of service references, although it may contain less than that number. The value input to this argument must be positive, otherwise an `IllegalArgumentException` will be thrown.

If the cache is empty, or if no service can be found that matches the input criteria, then the first form of `lookup` will return `null`; whereas the second form of `lookup` will return an empty array. The algorithm used to select the return element(s) from the set of matching service references is implementation dependent.

Neither form of the `lookup` method of the `LookupCache` interface returns a copy of the matching service reference(s) that were selected; rather, each form returns the actual service reference(s) from the cache itself. Because the actual service reference(s) are returned, entities that invoke either form of this method must not modify the contents of the returned reference(s). Modifying the returned service reference(s) could cause the state of the cache to become corrupted or inconsistent. This potential for corruption or inconsistency is why the effects of modifying the service reference(s) returned by either form of `lookup` is undefined.

Typically, an entity will request the creation of a separate cache for each service type of interest. When the entity simply needs a reference to a service of a particular type, the entity should invoke the first form of `lookup` to retrieve one element from the cache; in this case, which particular service reference that is returned will not, in general, matter to the entity. If for some reason it does matter to an entity which service reference is returned, then the entity can invoke the second form of `lookup` requesting that `Integer.MAX_VALUE` service references be returned; doing so will return all elements of the cache that match the input criteria. The entity can then iterate through each element, selecting the desired reference.

The `addListener` method will register a `ServiceDiscoveryListener` object with the event mechanism of a `LookupCache`. This listener object will receive a `ServiceDiscoveryEvent` upon the discovery, removal, or modification of one of the cache's services, as described previously in the section titled *Events and the Cache*. This method takes one argument: a reference to the `ServiceDiscoveryListener` object to register.

Once a listener is registered, it will be notified of all service references discovered to date, and will be notified as new services are discovered and existing services are modified or discarded. If the parameter value is `null`, no action will be taken.

The `LookupCache` makes a re-entrancy guarantee with respect to any `ServiceDiscoveryListener` objects registered with it. Should the `LookupCache` invoke a method on a registered listener (a local call), any call from that method to a local method of the `LookupCache` is guaranteed not to result in a deadlock condition.

The `removeListener` method will remove a `ServiceDiscoveryListener` object from the set of listeners currently registered with a `LookupCache`. Once all listeners are removed from the cache's set of listeners, the cache will send no more `ServiceDiscoveryEvent` notifications. This method takes one argument: a reference to the `ServiceDiscoveryListener` object to remove.

If the parameter value to `removeListener` is `null`, or if the listener passed to this method does not exist in the set of listeners maintained by the implementation class, then this method will take no action.

If an entity determines that a service reference retrieved from the cache is no longer available, the entity should request the removal of that reference from the cache. The mechanism for discarding an unavailable service from the cache is provided by the `discard` method of the `LookupCache` interface. The `discard` method takes one argument: an instance of `Object` whose reference is the service reference to remove from the cache. If the proxy input to this method is `null`, or if it matches (using the `equals` method) none of the service references in the cache, this method takes no action.

The `discard` method not only deletes the service reference from the cache, but also causes a notification to be sent to all registered listeners indicating that the service has been discarded (see the description of the `serviceRemoved` method in the section that specifies the `ServiceDiscoveryListener` interface). The service is guaranteed to have been removed from the cache when this method completes successfully; the service is then said to have been "discarded". No such guarantee is made with respect to when the discard event is sent to the client's registered listeners. That is, the event notifying the client that the service has been discarded may or may not be sent asynchronously.

Note that after the service has been discarded, there is no guarantee that the service will again become eligible for discovery. If the service's residency in at least one lookup service from the managed set ends (usually because the service's lease with that lookup service has expired), the service will be re-discovered when it becomes available and re-registers with that lookup service.

The `terminate` method performs cleanup duties related to the termination of the processing being performed by a particular instance of `LookupCache`. For that

instance, this method cancels all event leases granted by the lookup services that supplied the contents of the cache, and un-exports all remote listener objects registered with those lookup services. The `terminate` method is typically called when the entity is no longer interested in the contents of the `LookupCache`.

---

# The LookupDiscoveryService

## 8.1 Overview

Part of the *Jini™ Discovery and Join Specification* is devoted to defining the discovery requirements for well-behaved Jini clients and services, called *discovering entities*, which are required to participate in the multicast discovery protocol. Discovering entities are required to send multicast discovery requests to lookup services with which the entities wish to interact. In addition, they must continuously listen for and act on announcements from the desired lookup services. Interactions with a discovered lookup service may involve registration with that lookup service, or may simply involve querying the lookup service for services of interest (or both). In order to find *specific* lookup services, discovering entities also need to be able to participate in the unicast discovery protocol.

Under certain circumstances, a discovering entity may find it useful to allow a third party to perform the entity's discovery duties. For example, an activatable entity that wishes to deactivate may wish to employ a special Jini service — referred to as a *lookup discovery service* — to perform discovery duties on its behalf. Such an entity may wish to deactivate for various reasons, one being to conserve computational resources. While the entity is inactive, the lookup discovery service, running on the same or a separate host, would employ the discovery protocols to find lookup services in which the entity has expressed interest, and would notify the entity when a previously unavailable lookup service has become available.

The facilities of the lookup discovery service are of particular value in a scenario where a new lookup service is added to a long-lived djinn containing multiple inactive services. Without the use of a lookup discovery service, the time

frame over which the new lookup service is fully populated can be unpredictable and unbounded.

Because an inactive service has no way of discovering a new lookup service, each inactive service wishing to discover and join a new lookup service must first activate. Since activation of an inactive service occurs when some client attempts to use the service, the amount of time that passes between the arrival of the new lookup service and the activation of the service can vary greatly over the range of services. Thus, the time frame over which the lookup service becomes fully populated is unpredictable since it could take arbitrarily long before all of the services activate and then discover and join the new lookup service.

The time frame over which the lookup service becomes fully populated is not only unpredictable, it is also unbounded because there is no guarantee that the lookup service will send multicast announcements between the time the service activates and the time it deactivates. If the timing is right, it is possible that one or more of the services may never discover and join the new lookup service. Thus, without the use of the lookup discovery service, the new lookup service may never fully populate.

As another example of a discovering entity that may find it useful to allow a third party to perform the entity's discovery duties, consider an entity that exists in an environment with one of the following characteristics:

- ◆ The environment does not support multicast.
- ◆ The environment contains no lookup services within the entity's *multicast radius*.
- ◆ The environment does contain lookup service(s) within the entity's multicast radius, but at least one service needed by the entity is not registered with any lookup service within that radius.

If such an entity was provided with references to lookup services — located outside of the entity's multicast radius — which contain services needed by the entity, the entity could contact each lookup service and retrieve the desired service references. One way to provide the entity with access to those lookup services, might be to configure the entity to find and use a lookup discovery service that would employ multicast discovery to find nearby lookup services belonging to groups in which the entity has expressed interest. After acquiring references to the targeted lookup services, the lookup discovery service would pass those references to the entity, providing the entity with access to the services registered with each lookup service. In this way, the entity participates in the multicast discovery protocol through a proxy relationship with the lookup discovery service, gaining

access not only to each discovered lookup service but also to all of their registered services.

Note that the scenario just described does not come without restrictions. In order for the lookup discovery service to be able to “link” an entity with lookup services in the way just described, the lookup discovery service must be registered with a lookup service having a location that is either known to the entity, or is within the multicast radius of the entity. Furthermore, the lookup discovery service must be running on a host that is located within the multicast radius of the lookup services with which the entity wishes to be linked. That is, the entity must be able to find the lookup discovery service, and the lookup discovery service must be able to find the other desired lookup services.

To address these scenarios, the lookup discovery service participates in both the multicast discovery protocol and the unicast discovery protocol on behalf of a registered discovering entity or *client*. This service will listen for and process multicast announcement packets from Jini lookup services, and will, until successful, repeatedly attempt to discover specific lookup services that the client is interested in finding.

Upon discovery of a previously undiscovered lookup service of interest, the lookup discovery service notifies all entities that have requested the discovery of that lookup service that such an event has occurred. The event mechanism employed by the lookup discovery service satisfies the requirements defined in the *Jini™ Distributed Event Specification*. Note that the entity that receives such an event notification does not have to be the client of the lookup discovery service; it may be a third-party event-handling service such as an event mailbox service. Once a client is notified of the discovery of a lookup service, it is left to the client to define the semantics of how it interacts with that lookup service. For example, the client may wish to join the lookup service, simply query it for other useful services, or both.

The lookup discovery service must be implemented as a well-behaved Jini service, and must comply with all of the policies embodied in the Jini technology programming model. Thus, the resources granted by this service are leased, and implementations of this service must adhere to the distributed leasing model for Jini technology as defined in the *Jini™ Distributed Leasing Specification*. That is, the lookup discovery service will only grant its services for a limited period of time without an active expression of continuing interest on the part of the client.

### 8.1.1 Goals & Requirements

The requirements of the interfaces and classes specified in this document are as follows:

- ◆ To define a service that not only employs the Jini discovery protocols to discover, by way of either group association or `LookupLocator` association, lookup services in which clients have registered interest, but also which notifies its clients of the discovery of those lookup services
- ◆ To provide this service in such a way that it can be used by entities that deactivate
- ◆ To comply with the policies embodied in the Jini technology programming model

The goals of this document are as follows:

- ◆ To describe the lookup discovery service
- ◆ To provide guidance in the use and deployment of services that implement the `LookupDiscoveryService` interface and its related classes and interfaces

## 8.2 Other Types

The types defined in the specification of the `LookupDiscoveryService` interface are in the `net.jini.discovery` package. The following object types may be referenced in this chapter. Whenever referenced, these object types will be referenced in unqualified form:

```
net.jini.core.discovery.LookupLocator
net.jini.core.event.EventRegistration
net.jini.core.event.RemoteEventListener
net.jini.core.lease.Lease
net.jini.core.lookup.ServiceRegistrar
net.jini.discovery.DiscoveryEvent
net.jini.discovery.DiscoveryGroupManagement
net.jini.discovery.DiscoveryListener
java.io.IOException
java.rmi.MarshalledObject
java.rmi.NoSuchObjectException
java.rmi.RemoteException
```

## 8.3 The Interface

The `LookupDiscoveryService` interface defines the service introduced in the previous sections of this chapter. Through this interface, other Jini services and

clients may request that discovery processing be performed on their behalf. This interface belongs to the `net.jini.discovery` package, and any service implementing this interface must comply with the definition of a Jini service. This interface is not a remote interface; each implementation of this service exports front-end proxy objects that implement this interface local to the client, using an implementation-specific protocol to communicate with the actual remote server (the back-end). All of the proxy methods must obey normal Java Remote Method Invocation (RMI) remote interface semantics except where explicitly noted. Two proxy objects are equal (using the `equals` method) if they are proxies for the same lookup discovery service.

The one method defined in this interface throws a `RemoteException`, and only requires the default serialization semantics so that this interface can be implemented directly using Java RMI.

```
package net.jini.discovery;

public interface LookupDiscoveryService
{
    public LookupDiscoveryRegistration register
        (String[] groups,
         LookupLocator[] locators,
         RemoteEventListener listener,
         MarshallableObject handback,
         long leaseDuration)
        throws RemoteException;
}
```

When requesting a registration with the lookup discovery service, the client indicates the lookup services it is interested in discovering by submitting two sets of objects. Each set may contain zero or more elements. One set consists of the names of the groups whose members are lookup services the client wishes to be discovered. The other set consists of `LookupLocator` objects, each corresponding to a specific lookup service the client wishes to be discovered.

For each successful registration, the lookup discovery service will manage both the set of group names and the set of locators submitted. These sets will be referred to as the *managed set of groups*, and the *managed set of locators*, respectively. The managed set of groups associated with a particular registration contains the names of the groups whose members consist of lookup services that the client wishes to be discovered through *multicast* discovery. Similarly, the managed set of locators contains instances of `LookupLocator`, each corresponding to a specific lookup service that the client wishes to be discovered through *unicast* discovery. The references to the lookup services that have been discovered will be

maintained in a set referred to as the *managed set of lookup services* (or managed set of *registrars*).

Note that when the general term *managed set* is used, it should be clear from the context whether groups, locators, or registrars are being discussed. Furthermore, when the term *group discovery* or *locator discovery* is used, it should be taken to mean, respectively, the employment of either the multicast discovery protocol or the unicast discovery protocol to discover lookup services that correspond to members of the appropriate managed set.

## 8.4 The Semantics

In order to employ the lookup discovery service to perform discovery on its behalf, a client must first register with the lookup discovery service by invoking the `register` method defined in the `LookupDiscoveryService` interface. The `register` method is the only method specified by this interface.

An invocation of the `register` method produces an object — referred to as a registration object (or simply, a *registration*) — that is mutable. That is, the registration object contains methods through which it may be changed. Because the returned object is mutable, each invocation of the `register` method produces a new registration object. Thus, the `register` method is not idempotent.

The `register` method may throw a `RemoteException`. Typically, this exception occurs when there is a communication failure between the client and the lookup discovery service. When this exception does occur, the registration may or may not have been successful.

Each registration with the lookup discovery service is persistent across restarts (or crashes) of the lookup discovery service, until the lease on the registration expires or is cancelled.

The `register` method takes the following as arguments:

- ◆ A `String` array, none of whose elements may be `null`, consisting of zero or more names of the groups to which the desired lookup services belong
- ◆ An array of zero or more non-`null` `LookupLocator` objects, each corresponding to a specific lookup service the client wishes to be discovered
- ◆ A non-`null` `RemoteEventListener` object which specifies the entity that will receive events notifying the registration of the discovery of lookup services of interest
- ◆ Either `null` or an instance of `MarshaledObject` specifying an object that will be included in the notification event that the lookup discovery service sends to the registered listener

- ◆ A long value representing the amount of time (in milliseconds) for which the resources of the lookup discovery service are being requested

The `register` method returns an object that implements the `LookupDiscoveryRegistration` interface. It is through this returned object that the client interacts with the lookup discovery service. This interaction includes activities such as group and locator management, state retrieval, and discarding discovered but unavailable lookup services so they are eligible for re-discovery. The semantics of the methods of the `LookupDiscoveryRegistration` interface are defined in the next section.

The `groups` argument takes a `String` array, none of whose elements may be `null`. Although it is acceptable to input `null` (equivalent to `DiscoveryGroupManagement.ALL_GROUPS`) for the `groups` argument itself, if the argument contains one or more `null` elements, a `NullPointerException` is thrown. If the value is `null`, the lookup discovery service will attempt to discover all lookup services located within the multicast radius of the host on which the lookup discovery service is running. If an empty array (equivalent to `DiscoveryGroupManagement.NO_GROUPS`) is passed in, then no group discovery will be performed for the associated registration until the client, through one of the registration's methods, populates the managed set of groups.

The `locators` argument takes an array of `LookupLocator` objects, none of whose elements may be `null`. If either the empty array or `null` is passed in as the `locators` argument, then no locator discovery will be performed for the associated registration until the client, through one of the registration's methods, populates the managed set of locators. Although it is acceptable to input `null` for the `locators` argument itself, if the argument contains one or more `null` elements, a `NullPointerException` is thrown.

Upon discovery of a lookup service, through either group discovery or locator discovery, the lookup discovery service will send an event, referred to as a *discovery event*, to the listener associated with the registration produced by the call to `register`.

After initial discovery of a lookup service, the lookup discovery service will continue to monitor the state of the multicast announcements from that lookup service. Depending on the state of those announcements, the lookup discovery service may send either a discovery event or an event referred to as a *discard event*. The conditions under which either a discovery event or a discard event will be sent are as follows:

- ◆ If the multicast announcements from an already discovered lookup service indicate that the lookup service is a member of a new group, a discovery

event will be sent to all registrations that have registered interest in lookup services belonging to that group.

- ◆ If the multicast announcements from an already discovered lookup service indicate that the lookup service is no longer a member of one or more of the groups that had been reflected in previous multicast announcements, a discard event will be sent to all registrations that have registered interest in at least one of the missing groups but in none of the remaining groups.
- ◆ If the multicast announcements from an already discovered lookup service are no longer being received, a discard event will be sent to all registrations that have registered interest in that lookup service.

---

**Note:** The requirement that the lookup discovery service monitor the state of the multicast announcements from already-discovered lookup services is very desirable because it allows for the maintenance of consistent state. But if we do include such a requirement, then the `LookupDiscovery` utility will have to be changed in a similar fashion.

---

A more detailed discussion of the event semantics of the lookup discovery service is presented next in the section titled *Event Semantics*.

A valid parameter must be passed as the `listener` argument to the `register` method. If a `null` value is input to this argument, then a `NullPointerException` will be thrown and the registration fails.

The state information maintained by the lookup discovery service includes the set of group names, locators, and listeners submitted by each client through each invocation of the `register` method, with duplicates eliminated. This state information contains no knowledge of the clients that register with the lookup discovery service. Thus, there is no requirement that a client identify itself during the registration process.

## Event Semantics

For each registration created by the lookup discovery service, an event identifier will be generated that uniquely maps the registration to the listener and to the registration's managed set of groups and managed set of locators. This event identifier is returned as a part of the returned registration object, and is unique across all other active registrations with the lookup discovery service.

Whenever the lookup discovery service finds a lookup service matching the discovery criteria of one or more of its registrations, it sends an instance of `RemoteDiscoveryEvent` (a sub-class of `RemoteEvent`) to the listener correspond-

ing to each such registration. The event sent to each listener will contain the appropriate event identifier.

Once an event signaling the discovery (by group or locator) of a desired lookup service has been sent, no other discovery events for that lookup service will be sent to a registration's listener until the lookup service is discarded (through that registration) and then re-discovered. Note that a detailed definition of what it means for the lookup discovery service to discard a lookup service is presented later in this document.

If, between the time a lookup service is discarded (through any registration) and the time it is re-discovered, a new registration having parameters referencing that lookup service is requested, upon re-discovery of the lookup service an event will also be sent to that new registration's listener.

The sequence numbers for a given event identifier are *strictly increasing* (as defined in the *Jini™ Distributed Event Specification*), which means that when any two such successive events have sequence numbers differing by only a value of 1, then no events have been missed. On the other hand, when viewing the set of received events in order, if the difference between the sequence numbers of two successive events is greater than 1, then one or more events may or may not have been missed. For example, a difference greater than 1 could occur if the lookup discovery service crashes, even if no events are lost because of the crash. When two such successive events have sequence numbers whose difference is greater than 1, there is said to be a *gap* between the events.

When a gap occurs between events, the local state related to the discovered lookup services may or may not fall "out of sync" with the corresponding remote state. For example, if the gap corresponds to a missed event representing the (initial) discovery of a targeted lookup service, the remote state will reflect this discovery whereas the local state will not. To allow clients to identify and correct such a situation, each registration object provides a method which returns a set consisting of the proxies to the lookup services that have been discovered for that registration. With this information, the client can update its local state.

When requesting a registration with the lookup discovery service, a client may also supply a reference to an object (as a parameter to the registration method), wrapped in a `MarshaledObject`, referred to as a *handback*. When the lookup discovery service sends an event to a registration's listener, the event will also contain a reference to this handback object. The lookup discovery service will not change the handback object. That is, the handback object contained in the event sent by the lookup discovery service will be identical to the handback object registered by the client with the event mechanism.

The semantics of the object input to the handback argument are left to each client to define, although `null` may be input to this argument. The role of the

handback object in the remote event mechanism is detailed in the *Jini™ Distributed Event Specification*.

### Leasing Semantics

When a client registers with the lookup discovery service, it is effectively requesting a lease on the resources provided by that service. The initial duration of the lease granted to a client by the lookup discovery service will be less than or equal to the requested duration reflected in the value input to the `LeaseDuration` argument. That value must be positive, `Lease.FOREVER`, or `Lease.ANY`. If any other value is input to this argument, an `IllegalArgumentException` will be thrown. The client may obtain a reference to the `Lease` object granted by the lookup discovery service through the associated registration returned by the service.

## 8.5 Supporting Interfaces and Classes

The `LookupDiscoveryService` interface references the `LookupDiscoveryRegistration` interface, defined next. This class also depends on the concrete classes `RemoteDiscoveryEvent` and `LookupUnmarshalException` defined later in this section.

### 8.5.1 The LookupDiscoveryRegistration Interface

When a client requests a registration with a lookup discovery service, an object that implements the `LookupDiscoveryRegistration` interface is returned. It is through this interface that the client manages the parameters reflected in the registration with the lookup discovery service.

```
package net.jini.discovery;

public interface LookupDiscoveryRegistration
{
    public EventRegistration getEventRegistration();
    public Lease getLease();
    public ServiceRegistrar[] getRegistrars()
                                throws LookupUnmarshalException,
                                    RemoteException;
    public String[] getGroups() throws RemoteException;
    public LookupLocator[] getLocators()
```

```

        throws RemoteException;

    public void addGroups(String[] groups)
        throws RemoteException;
    public void setGroups(String[] groups)
        throws RemoteException;
    public void removeGroups(String[] groups)
        throws RemoteException;

    public void addLocators(LookupLocator[] locators)
        throws RemoteException;
    public void setLocators(LookupLocator[] locators)
        throws RemoteException;
    public void removeLocators(LookupLocator[] locators)
        throws RemoteException;

    public void discard(ServiceRegistrar registrar)
        throws RemoteException;
}

```

As with the `LookupDiscoveryService` interface, the `LookupDiscoveryRegistration` interface is not a remote interface. Each implementation of the lookup discovery service exports proxy objects that implement this interface local to the client, using an implementation-specific protocol to communicate with the actual remote server. All of the proxy methods must obey normal Java RMI remote interface semantics except where explicitly noted. Two proxy objects are equal (using the `equals` method) if they are proxies for the same registration created by the same lookup discovery service.

The discovery facility of the lookup discovery service, together with its event mechanism, make up the set of resources clients register to use. Because the resources of the lookup discovery service are leased, access is granted for only a limited period of time, unless there is an active expression of continuing interest on the part of the client.

When a client uses the registration process to request that a lookup discovery service perform discovery of a set of desired lookup services, the client is also registered with the service's event mechanism. Because of this implicit registration, the lookup discovery service "bundles" both resources under a single lease. When that lease expires, both discovery processing and event notifications will cease with respect to the registration that resulted from the client's request.

To facilitate lease management and event handling, the `LookupDiscoveryRegistration` interface defines methods which allow the cli-

ent to retrieve its event registration information. Additional methods defined by this interface allow the client to retrieve proxies to the registration's currently discovered lookup services, as well as to modify the managed sets of groups and locators.

If the client's registration with the lookup discovery service has expired or been cancelled, then any invocation of a remote method defined in this interface will result in a `NoSuchObjectException`. That is, any method that communicates with the back-end server of the lookup discovery service will throw a `NoSuchObjectException` if the registration on which the method is invoked no longer exists. It should be noted that if a client receives a `NoSuchObjectException` as a result of an invocation of such a method, although the client can assume that the registration no longer exists, the client cannot assume that the lookup discovery service itself no longer exists.

Each remote method of this interface may throw a `RemoteException`. Typically, this exception occurs when there is a communication failure between the client and the lookup discovery service. Whenever this exception occurs as a result of the invocation of one of these methods, the method may or may not have completed its processing successfully.

## **The Semantics**

The methods defined by this interface are organized into a set of accessor methods, a set of group mutator methods, a set of locator mutator methods, and the `discard` method. Through the accessor methods, various elements of a registration's state can be retrieved. The mutator methods provide a mechanism for changing the set of groups and locators to be discovered for the registration. Through the `discard` method, a particular lookup service may be made eligible for re-discovery.

### The Accessor Methods

The `getEventRegistration` method returns an `EventRegistration` object that encapsulates the information needed by the client to identify a notification sent by the lookup discovery service to the registration's listener. This method is not remote and takes no arguments.

The `getLease` method returns the `Lease` object that controls a client's registration with the lookup discovery service. It is through the `Lease` object returned by this method that the client requests the renewal or cancellation of the registration with the lookup discovery service. This method is not remote and takes no arguments.

Note that the object returned by the `getEventRegistration` method also provides a `getLease` method. That method and the `getLease` method defined by the `LookupDiscoveryRegistration` interface both return the same `Lease` object. The `getLease` method defined here is provided as a convenience to avoid the indirection associated with the `getLease` method on the `EventRegistration` object, as well as to avoid the overhead of making two method calls.

The `getRegistrars` method returns a set of instances of the `ServiceRegistrar` interface. Each element in the set is a proxy to one of the lookup services that have already been discovered for the registration. Additionally, each element in the set will be unique with respect to all other elements in the set, as determined by the `equals` method provided by each element. The contents of the set make up the remote state of the registration's currently discovered lookup services.

This method can be used to maintain synchronization between the set of discovered lookup services making up a registration's local state on the client and the registration's corresponding remote state maintained by the lookup discovery service. The local state can become un-synchronized with the remote state when a gap occurs in the events received by the registration's listener.

According to the event semantics previously described, if there is no gap between two sequence numbers, no events have been missed and the states remain synchronized with each other; if there is a gap, events may or may not have been missed. Thus, upon finding gaps in the sequence of events, the client can invoke this method and use the returned information to synchronize the local state with the remote state.

In order to construct its return set, the `getRegistrars` method retrieves from the lookup discovery service the set of proxies making up the registration's current remote state. When the lookup discovery service sends the requested set of proxies, the set is sent as a set of marshalled instances of the `ServiceRegistrar` interface. The lookup discovery service individually marshals each proxy in the set that it sends because if it were not to do so, *any* deserialization failure on the set would result in an `IOException`, and failure would be declared for the whole deserialization process, not just an individual element. This would mean that all elements of the set sent by the lookup discovery service — even those that were successfully deserialized — would be unavailable to the client. Individually marshalling each element in the set minimizes the “all or nothing” aspect of the deserialization process, allowing the client to recover those proxies that can be successfully unmarshalled and to proceed with processing that might not be possible otherwise.

When constructing the return set, this method attempts to unmarshal each element of the set of marshalled proxy objects sent by the lookup discovery service. When failure occurs while attempting to unmarshal any of the elements of the set

sent by the lookup discovery service, this method throws an exception of type `LookupUnmarshalException` (described later). It is through the contents of this exception that the client can recover any available proxies and perform error handling related to the unavailable proxies. The contents of the `LookupUnmarshalException` provide the client with the following useful information:

- ◆ The knowledge that a problem has occurred while unmarshalling at least one of the elements making up the remote state of the registration's discovered lookup services
- ◆ The set of proxy objects that were successfully unmarshalled by the `getRegistrars` method
- ◆ The set of marshalled proxy objects that could not be unmarshalled by the `getRegistrars` method
- ◆ The set of exceptions corresponding to each failed attempt at unmarshalling

The type of exception that occurs when attempting to unmarshal an element of the set sent by the lookup discovery service is typically an `IOException` or a `ClassNotFoundException` (usually the more common of the two). A `ClassNotFoundException` occurs whenever a remote object on which the marshalled proxy depends cannot be retrieved and loaded — usually because the codebase of one of the object's classes or interfaces is currently 'down'. To address this situation, the client may wish to proceed with its processing using the successfully unmarshalled proxies, and attempt to unmarshal the unavailable proxies at some later time.

If the `getRegistrars` method returns successfully without throwing a `LookupUnmarshalException`, the client is guaranteed that all marshalled proxies belonging to the set sent by the lookup discovery service have each been successfully unmarshalled; the client then has a current and complete view of the remote state of the lookup services discovered for the associated registration.

The `getGroups` method returns an array consisting of the group names from the registration's managed set. If the managed set of groups is empty, this method returns the empty array (equivalent to `DiscoveryGroupManagement.NO_GROUPS`). If there is no managed set of groups associated with the registration, then this method returns `null` (equivalent to `DiscoveryGroupManagement.ALL_GROUPS`).

The `getLocators` method returns an array consisting of the `LookupLocator` objects from the registration's managed set. If the managed set of locators is empty, this method returns the empty array. If there is no managed set of locators associated with the registration, then `null` is returned.

## The Group Mutator Methods

With respect to a particular registration, the groups to be discovered may be modified using the methods described in this section. In each case, a set of groups is represented as a `String` array, none of whose elements may be `null`. If any set of groups input to one of these methods contains one or more `null` elements, a `NullPointerException` is thrown. The empty set is denoted by the empty array (`DiscoveryGroupManagement.NO_GROUPS`), and “no set” is indicated by `null` (`DiscoveryGroupManagement.ALL_GROUPS`). No set indicates that all lookup services within the multicast radius should be discovered. Invoking any of these methods with an input set of groups that contains duplicate names is equivalent to performing the invocation with the duplicate group names removed from the input set.

The `addGroups` method adds a set of group names to the registration’s managed set. This method takes one argument: a `String` array consisting of the set of group names with which to augment the managed set.

Elements in the array that duplicate elements already in the managed set will be ignored. Once a new name has been added to the managed set, the lookup discovery service will attempt to discover all as yet undiscovered lookup services that are members of the group having that name.

If the registration has no current managed set of groups to augment, this method throws an `UnsupportedOperationException`. If the parameter value is `null`, this method throws a `NullPointerException`. If the parameter value is the empty array, then the registration’s managed set of groups will not change.

The `setGroups` method replaces all of the group names in the registration’s managed set with names from a new set. This method takes one argument: a `String` array consisting of the set of new group names that will replace the set of names in the managed set.

Once a new group name has been placed in the managed set, if there are lookup services belonging to that group that have already been discovered, no event will be sent to the registration’s listener for those particular lookup services. Attempts to discover any undiscovered lookup services belonging to that group will continue to be made for the registration.

If `null` is passed to `setGroups`, then the lookup discovery service will attempt to discover any undiscovered lookup services located within the multicast radius and, upon discovery of a lookup service, will send to the registration’s listener an event signaling that discovery. If the parameter value is the empty array, then group discovery for the registration will cease.

The `removeGroups` method deletes a set of group names from the registration’s managed set. This method takes one argument: a `String` array containing the set of group names to remove.

If the registration has no current managed set of groups from which to remove elements, the `removeGroups` method throws an `UnsupportedOperationException`. If `null` is input, this method throws a `NullPointerException`. For any element in the input set that equals no element in the managed set, `removeGroups` takes no action with respect to that element. If the empty array is input, then the registration's managed set of groups will not change.

After a set of groups has been removed from the managed set because of an invocation of either `setGroups` or `removeGroups`, attempts to discover any lookup service that meets all of the following criteria will cease to be made for the registration:

- ◆ the lookup service is a member of one or more of the groups that were removed from the registration's managed set, and
- ◆ the lookup service is not a member of any group in the new managed set resulting from the invocation of `setGroups` or `removeGroups`, and
- ◆ the lookup service does not correspond to any element in the registration's managed set of locators.

### The Locator Mutator Methods

With respect to a particular registration, the set of locators to discover may be modified using the methods described in this section. In each case, a set of locators is represented as an array of `LookupLocator` objects, none of whose elements may be `null`. If any set of locators input to one of these methods contains one of more `null` elements, a `NullPointerException` is thrown. Invoking any of these methods with a set of locators that contains duplicate locators (as determined by the `equals` method of `LookupLocator`) is equivalent to performing the invocation with the duplicates removed from the input set.

The `addLocators` method adds a set of `LookupLocator` objects to the registration's managed set. This method takes one argument: an array consisting of the set of locators with which to augment the managed set. Elements in the input set that duplicate (using `LookupLocator.equals`) elements already in the managed set will be ignored.

This method throws an `UnsupportedOperationException` if the registration has no managed set of locators to augment. If `null` is passed to `addLocators`, a `NullPointerException` will be thrown. If the empty array is the parameter value, the registration's managed set of locators will not change.

The `setLocators` method replaces all of the locators in the registration's managed set with `LookupLocator` objects from a new set. This method takes one

argument: an array consisting of the set of locators that will replace the locators in the managed set.

If `null` is passed to `setLocators`, a `NullPointerException` will be thrown. If the parameter value is the empty array, all locator discovery performed by the lookup discovery service, for the registration, will cease.

The `removeLocators` method deletes a set of `LookupLocator` objects from the registration's managed set. This method takes one argument: an array containing the locators to remove.

If the registration has no managed set of locators from which to remove elements, this method throws an `UnsupportedOperationException`. If `null` is passed to `removeLocators`, a `NullPointerException` will be thrown. For any element in the input set that equals no element in the managed set, `removeLocators` takes no action with respect to that element. If the parameter value is the empty array, the registration's managed set of locators will not change.

Whenever a new locator is placed in the managed set as a result of an invocation of one of the locator mutator methods, and that new locator equals none of the locators corresponding to the previously discovered lookup services (across all registrations), the lookup discovery service will attempt unicast discovery of the lookup service associated with the new locator. Note that locator equality is determined by the `equals` method of `LookupLocator`.

If locator discovery is attempted, the discovery attempt will be repeated until one of the following events occurs:

- ◆ The lookup service is discovered
- ◆ The client's lease expires
- ◆ The client explicitly removes the locator from the managed set

Upon discovery of the lookup service corresponding to the new locator, or upon finding a match between the new locator and a previously discovered lookup service, an event signaling a discovery will be sent to the registration's listener.

Whenever an existing locator is removed from the managed set as a result of an invocation of one of the methods above, the action taken by the lookup discovery service depends on whether the lookup service corresponding to that locator had been previously discovered for the registration. Furthermore, if it was previously discovered, the action taken is also dependent on the discovery protocol through which the discovery occurred. With respect to the lookup service corresponding to such a removed locator, the action taken by the lookup discovery service can be described as follows:

- ◆ If the lookup service has yet to be discovered for the registration, attempts to perform locator discovery of that lookup service will cease.
- ◆ If the lookup service has already been discovered for the registration through locator discovery, but not through group discovery, the lookup service will be *discarded* (as defined below).

---

**Note:** The semantics of the locator methods above were specified to be consistent with the group methods of this service as well as the methods of the `LookupDiscovery` utility. We need to modify the methods of the `LookupLocatorDiscovery` utility to be similarly consistent.

---

### Discarding Lookup Services

When the lookup discovery service removes an already discovered lookup service from a registration's managed set(s) and makes the lookup service eligible for re-discovery, the lookup service is considered to be *discarded*.

There are a number of situations where the lookup discovery service will discard a lookup service:

- ◆ In response to a discard request resulting from an invocation of a registration's `discard` method
- ◆ When a lookup service—previously discovered through *locator* discovery—is removed from a registration's managed set, in response to an invocation of either the `setLocators` method or the `removeLocators` method
- ◆ When the multicast announcements from an already discovered lookup service indicate that the lookup service is no longer a member of one or more of the groups reflected in its previous multicast announcements, and at least one registration has registered interest in one or more of the missing groups but in none of the remaining groups reflected in those announcement.
- ◆ When the multicast announcements from an already discovered lookup service are no longer being received

For each of these cases, whenever the lookup discovery service discards a lookup service, it will send an event to the registration's listener to notify it that the lookup service has been discarded.

The `discard` method provides a mechanism for registered clients to inform the lookup discovery service of the existence of an unavailable lookup service, and to request that the lookup discovery service discard that lookup service.

The `discard` method takes a single argument: the proxy to the lookup service to discard. This method takes no action if the parameter to this method equals none of the proxies reflected in the managed set (using proxy equality as defined in the *Jini™ Lookup Service Specification*). If `null` is passed to `discard`, a `NullPointerException` will be thrown.

Note that if a lookup service crashes or is unavailable for some reason, there will be no automatic notification of the occurrence of such an event. This means that for each of the registration's targeted lookup services, after a lookup service is initially discovered, the lookup discovery service will not attempt to discover that lookup service again (for that registration) until that lookup service is discarded.

When a client determines that a lookup service discovered for a registration is no longer available, it is the responsibility of the client to inform the lookup discovery service — through the invocation of the registration's `discard` method — that the previously discovered lookup service is no longer available, and that attempts should be made to re-discover that lookup service for the registration. Typically, a client determines that a lookup service is unavailable when the client attempts to use the lookup service but receives a *non-fatal* exception or error (e.g., `RemoteException`) as a result of the attempt.

Note that the lookup discovery service may be acting on behalf of numerous clients having access to the same lookup service. If that lookup service becomes unavailable, many of those clients may invoke `discard` between the time the lookup service becomes unavailable and the time it is re-discovered. Upon the first invocation of `discard`, the lookup discovery service will re-initiate discovery of the relevant lookup service for the registration of the client that made the invocation. For all other invocations made prior to re-discovery, the registrations through which the invocation is made are added to the list of registrations that will be notified when re-discovery of the lookup service does occur. That is, upon re-discovery of the lookup service, only those registrations through which this method is invoked will be notified.

Upon successful completion of the `discard` method, the proxy requested to be discarded is guaranteed to have been removed from the managed set associated with the registration through which each invocation was made. No such guarantee is made with respect to when the discard event is sent to each such registration's listener. That is, the event notifying the listeners that the service has been discarded may or may not be sent asynchronously.

### 8.5.2 The `RemoteDiscoveryEvent` Class

When the lookup discovery service discovers or discards a lookup service matching the criteria established through one of its registrations, the lookup discovery

service sends an instance of the `RemoteDiscoveryEvent` class to the `RemoteEventListener` implemented by the client and registered with the lookup discovery service.

```
package net.jini.discovery;

public class RemoteDiscoveryEvent extends RemoteEvent
{
    public RemoteDiscoveryEvent(Object source,
                                long eventID,
                                long seqNum,
                                MarshallableObject handback,
                                boolean discarded,
                                ServiceRegistrar[] registrars)
        throws IOException;

    public boolean isDiscarded();
    public ServiceRegistrar[] getRegistrars()
        throws LookupUnmarshalException,
               RemoteException;
}
```

`RemoteDiscoveryEvent` is a subclass of `RemoteEvent`, adding the following additional items of abstract state: a boolean indicating whether the lookup services referenced by the event have been discovered or discarded; and a set of marshalled instances of the `ServiceRegistrar` interface, having the characteristic that when each element is unmarshalled, the result is a proxy to one of the recently discovered or discarded lookup services. Methods are defined through which this additional state may be retrieved upon receipt of an instance of this class.

Clients need to know not only when a targeted lookup service has been discovered, but also when it has been discarded. The lookup discovery service uses an instance of `RemoteDiscoveryEvent` to notify a client's registration(s) when either of these events occurs, as indicated by the value of the boolean state variable. When the value of that variable is *true*, the event is referred to as a *discard event*; when *false*, it is referred to as a *discovery event*.

## The Semantics

The constructor of the `RemoteDiscoveryEvent` class takes the following parameters as input:

- ◆ A reference to the lookup discovery service that generated the event
- ◆ The event identifier that maps a particular registration to both its listener and its targeted groups and locators
- ◆ The sequence number of the event being constructed
- ◆ The client-defined handback (which may be null)
- ◆ A flag indicating whether the event being constructed is a discovery event or a discard event
- ◆ An array, none of whose elements may be null, containing the proxies to newly discovered or discarded lookup service(s)

If the empty array is input to the `registrars` parameter, the constructor will throw an `IllegalArgumentException`. If null is input to the `registrars` parameter, or if any of the elements of the `registrars` parameter is null, the constructor will throw a `NullPointerException`. If failure occurs when attempting to serialize every element of the `registrars` parameter, the constructor will throw an `IOException`.

The `isDiscarded` method returns a boolean that indicates whether the event is a discovery event or a discard event. If the event is a discovery event, then this method returns false. If the event is a discard event, true is returned.

The `getRegistrars` method returns an array consisting of instances of the `ServiceRegistrar` interface. Each element in the returned set is a proxy to one of the newly discovered or discarded lookup services that caused an instance of `RemoteDiscoveryEvent` to be sent. Additionally, each element in the returned set will be unique with respect to all other elements in the set, as determined by the `equals` method provided by each element. This method does not make a remote call. With respect to multiple invocations of this method, each invocation will return a new array.

When the lookup discovery service sends an instance of `RemoteDiscoveryEvent` to the listener of a client's registration, the set of lookup service proxies contained in the event consists of marshalled instances of the `ServiceRegistrar` interface. The lookup discovery service individually marshals each proxy associated with the event because if it were not to do so, *any* deserialization failure on the set would result in an `IOException`, and failure would be declared for the whole deserialization process, not just an individual element. This would mean that all elements of the set sent in the event — even those that can be successfully deserialized — would be unavailable to the client through this method. Just as with the `getRegistrars` method defined by the `LookupDiscoveryRegistration` interface, individually marshalling each element in the set minimizes the “all or nothing” aspect of the deserialization process, allowing the client to recover those

proxies that can be successfully unmarshalled and to proceed with processing that might not be possible otherwise.

When constructing the return set, this method attempts to unmarshal each element of the set of marshalled proxy objects contained in the event. When failure occurs while attempting to unmarshal any of the elements of that set, this method throws an exception of type `LookupUnmarshalException`. It is through the contents of this exception that the client can recover any available proxies and perform error handling with respect to the unavailable proxies.

If the `getRegistrars` method returns successfully without throwing a `LookupUnmarshalException`, the client is guaranteed that all marshalled proxies sent in the event have each been successfully unmarshalled during that particular invocation. Furthermore, after the first such successful invocation, no more unmarshalling attempts will be made (because such attempts are no longer necessary), and all future invocations of this method are guaranteed to return an array with contents identical to the contents of the array returned by the first successful invocation.

Note that an array, rather than a single proxy, is returned by the `getRegistrars` method so that implementations of the lookup discovery service can choose to “batch” the information sent to a registration. With respect to discoveries, batching the information may be particularly useful when a client first registers with the lookup discovery service.

Upon initial registration, multiple lookup services are typically found over a short period of time, providing the lookup discovery service with the opportunity to send all of the initially discovered lookup services in only one event. Afterwards, as so-called “late joiner” lookup services are found sporadically, the lookup discovery service may send events referencing only one lookup service. Note that the event sequence numbers, as defined earlier in this chapter in the section titled *Event Semantics*, are strictly increasing — even when the information is batched.

### 8.5.3 The `LookupUnmarshalException` Class

Recall that when unmarshalling an instance of `MarshaledObject`, one of the following checked exceptions is possible: an `IOException` can occur while deserializing the object from its internal representation; and a `ClassNotFoundException` can occur if, while deserializing the object from its internal representation, either the class file of the object cannot be found, or the class file of either an interface or a class referenced by the object being deserialized cannot be found. Typically, a `ClassNotFoundException` occurs when the codebase from which to retrieve the needed class file is not currently available.

The `LookupUnmarshalException` class provides a mechanism that clients of the lookup discovery service may use for efficient handling of the exceptions that may occur when unmarshalling elements of a set of marshalled instances of the `ServiceRegistrar` interface. When elements in such a set are unmarshalled, the `LookupUnmarshalException` class may be used to collect and report pertinent information; information generated when failure occurs during the unmarshalling process.

```
package net.jini.discovery;

public class LookupUnmarshalException extends Exception
{
    public LookupUnmarshalException
        (ServiceRegistrar[] unmarshalledRegs,
         MarshalledObject[] stillMarshalledRegs,
         Throwable[] exceptions);

    public ServiceRegistrar[] getUnmarshalledRegs();
    public MarshalledObject[] getStillMarshalledRegs();
    public Throwable[] getExceptions();
    public String getMessage();
}
```

The `LookupUnmarshalException` class is a subclass of `Exception`, adding the following additional items of abstract state:

- ◆ A set of `ServiceRegistrar` instances in which each element is the result of a successful unmarshalling attempt
- ◆ A set of marshalled instances of `ServiceRegistrar` in which each element could not be successfully unmarshalled
- ◆ A set of exceptions (`IOException`, `ClassNotFoundException`, or some unchecked exception) in which each element corresponds to one of the unmarshalling failures
- ◆ A `String` describing the nature of the exception

Note that because a `LookupUnmarshalException` should be thrown only as a result of a failure while unmarshalling a set of marshalled instances of `ServiceRegistrar`, no mechanism is provided to modify the initial value of the descriptive `String`.

Thus, when exceptional conditions occur while unmarshalling a set of marshalled instances of `ServiceRegistrar`, the `LookupUnmarshalException` class

can be used not only to indicate that an exceptional condition has occurred, but also to provide information that can be used to perform error handling activities such as: determining if it is feasible to continue with processing, reporting errors, attempting recovery, and debugging.

### The Semantics

The constructor of the `LookupUnmarshalException` class takes the following parameters as input:

- ◆ An array containing the set of instances of `ServiceRegistrar` that were successfully unmarshalled
- ◆ An array containing the set of marshalled `ServiceRegistrar` instances that could not be unmarshalled
- ◆ An array containing the set of exceptions that occurred during the unmarshalling process.

Each element in the `exceptions` parameter should be an instance of `IOException`, `ClassNotFoundException`, or some unchecked exception. Furthermore, there should be a one-to-one correspondence between each element in the `exceptions` parameter and each element in the `stillMarshalledRegs` parameter. That is, the element of the `exceptions` parameter corresponding to index  $i$  should be an instance of the exception that occurred while attempting to unmarshal the element at index  $i$  of the `stillMarshalledRegs` parameter.

If the number of elements in the `exceptions` parameter does not equal the number of elements in the `stillMarshalledRegs` parameter, the constructor will throw an `IllegalArgumentException`.

The `getUnmarshalledRegs` method is an accessor method that returns an array consisting of instances of `ServiceRegistrar`, where each element of the array corresponds to a successfully unmarshalled object. Note that the same array is returned on each invocation of this method; that is, a copy is not made.

The `getStillMarshalledRegs` method is an accessor method that returns an array consisting of instances of `MarshalledObject`, where each element of the array is a marshalled instance of the `ServiceRegistrar` interface, and corresponds to an object that could not be successfully unmarshalled. Note that the same array is returned on each invocation of this method; that is, a copy is not made.

The `getExceptions` method is an accessor method that returns an array consisting of instances of `Throwable`, where each element of the array corresponds to one of the exceptions that occurred during the unmarshalling process. Each ele-

ment in the return set should be an instance of `IOException`, `ClassNotFoundException`, or some unchecked exception. Additionally, there should be a one-to-one correspondence between each element in the array returned by this method and the array returned by the `getStillMarshaledRegs` method. Note that the same array is returned on each invocation of this method; that is, a copy is not made.

The `getMessage` method is an accessor method that returns a `String` describing the nature of the exception. Note that the same `String` is returned on each invocation of this method; that is, a copy is not made.

---

# The LeaseRenewalService

## 9.1 Overview

Leasing is a key concept in the Jini architecture. In general, Jini services only grant access to a resource for as long as the clients of those Jini services actively express interest in the resource being maintained. This pattern is in contrast to many other systems where access to a resource is granted until the client explicitly releases the resource. Using a leasing model generally makes a distributed system more robust by allowing stale information and services to be cleaned up, but it also places additional requirements on clients and services.

A client of a leased service may run into difficulties if it deactivates. Unless that client takes care to make sure some other process renews the client's leases while it is inactive or the client ensures that it is activated before its leases begin to expire, the client will lose access to the resources it has acquired. This loss can be particularly dramatic in the case of lookup service registrations. A service's registration with a lookup service is leased; if the service deactivates (maybe in order to conserve computational resources on its host) and it does not take appropriate steps, its registrations with lookups will expire, and before long it will be inaccessible. If the service only becomes active when clients require its services, it may never become active again, because at this point new clients may not be able to find it.

The need to renew leases creates a constant load on clients, servers, and the network. Although batching lease renewals can help (see the *Jini™ Distributed Leasing Specification*), a given client is unlikely to have very many leases granted by any one service at any given time, thus reducing the opportunities for meaningful batching.

This additional load may be an especially great burden on clients who always have the ability to access the network, but for various reasons cannot be continuously connected. A cell phone always has the ability to connect; however, being connected all the time will drain its batteries and accumulate airtime charges. One

or two leases may not pose a problem, but a large number of leases could force the phone to be on the network all the time.

A lease renewal service can help mitigate all of these problems. Services that wish to go quiescent (become inactive) can pass the responsibility for renewing the leases they have been granted to a renewal service. The service may then deactivate without risk of losing access to resources it has acquired. Clients that have continuous access to the network but cannot be continuously connected, such as the cell phone described above, can similarly register with a renewal service that can be continuously connected. The renewal service will renew the client's leases, allowing the client to remain disconnected most of the time. Lastly, if multiple clients pass their leases to a given renewal service, more opportunities for batching renewals will be created.

Like other Jini services, the lease renewal service will only grant its services for a limited period of time without an active expression of continuing interest. In order to break the recursive cycle that would otherwise result, the renewal service provides an optional event that is triggered before the leases that it grants expire. This event gives activatable processes that have deactivated the opportunity to wake up and renew their lease with the renewal service. Although it may seem odd for the lease renewal service to lease its services, it is very important that it does so. If it did not, then the lease renewal service could be used to subvert the leasing model.

A renewal service is likely to grant longer leases than other Jini services. In some cases, the lease may be so long that the client will not need to worry about renewing the lease at all. In other cases, the lease may be long enough that an activatable client that deactivates only rarely needs to reactivate solely to renew its lease with the renewal service. In any case, the leases that the renewal service grants are likely to be sufficiently long such that the actual renewal calls do not place an excessive load on the client, the renewal service, or the network.

### 9.1.1 Goals & Requirements

The requirements of the set of classes and interfaces in this chapter are:

- ◆ To provide a service for renewing leases
- ◆ To provide this service in such a way that it can be used by activatable processes that deactivate
- ◆ To provide these services in a way that does not overly weaken the leasing model

The goals of this chapter are:

- ◆ To describe the lease renewal service
- ◆ To provide guidance in the use and deployment of lease renewal services

## 9.2 Other Types

The types defined in the specification of the `LeaseRenewalService` interface are in the `net.jini.lease` package. The following object types may be referenced in this chapter. Whenever referenced, these object types will be referenced in unqualified form:

```
java.io.IOException  
java.rmi.MarshalledObject  
java.rmi.RemoteException  
java.rmi.NoSuchObjectException  
net.jini.core.lease.Lease  
net.jini.core.lease.UnknownLeaseException  
net.jini.core.event.RemoteEvent  
net.jini.core.event.RemoteEventListener  
net.jini.core.event.EventRegistration
```

## 9.3 The Interface

`LeaseRenewalService` (in the `net.jini.lease` package) defines the interface to the renewal service. The interface is not a remote interface; each implementation of the renewal service exports proxy objects that implement the `LeaseRenewalService` local to the client and use an implementation-specific protocol to communicate with the actual remote server. All of the proxy methods obey normal RMI remote interface semantics. Two proxy objects are equal (using the `equals` method) if they are proxies for the same renewal service. All of the methods of `LeaseRenewalService` throw `RemoteException` and only require the default serialization semantics. Therefore `LeaseRenewalService` can be implemented directly using RMI.

```
package net.jini.lease;  
  
public interface LeaseRenewalService {  
    public LeaseRenewalSet  
        createLeaseRenewalSet(long leaseDuration)  
        throws RemoteException;  
}
```

Clients of the renewal service organize the leases they wish to have renewed into *lease renewal sets* (or *sets* for short). A method is provided by the `LeaseRenewalService` interface to create these sets. These sets are then populated by methods defined on the sets themselves. Two leases in the same set need not be granted by the same process or have the same expiration time; in addition, they can be added or removed from the set independently.

When adding a lease to the set, the client specifies how long it should remain in the set by specifying a *membership duration*. The membership duration will be added to the current time to get a *membership expiration* for the lease. If the current time plus the membership duration is larger than `Long.MAX_VALUE`, the membership expiration will be `Long.MAX_VALUE`. When the lease's membership expiration arrives, the lease will be removed from the set without further client intervention. When renewing the lease, the renewal service will always ask for a duration that will end at the lease's current membership expiration. If `Lease.ANY` is specified for the membership duration, the membership expiration will be set to `Long.MAX_VALUE`; each time the lease is renewed, `Lease.ANY` will be the requested duration.

Each set is leased from the renewal service. If the lease on a set expires or is cancelled, the renewal service will destroy the set and take no further action with regard to the leases in the set. There is an event associated with each set that occurs at a client-specified time before the lease on the set expires. Clients can register for this event using methods provided by the set. A registration for this event does not have its own lease, but instead is bundled into the same lease under which the set was granted.

We use the term *definite exception* to refer to an exception that could be thrown by an operation (such as a remote method call) that would be indicative of a permanent failure. For purposes of this document, `NoSuchObjectException` and all non-`RemoteException` subtypes of `Throwable` are considered to be definite exceptions.

Conversely we use the term *indefinite exception* to refer to an exception that could be thrown by an operation that would be indicative of a transient failure. For purposes of this document all subtypes of `RemoteException` excluding `NoSuchObjectException` are considered indefinite exceptions.

Each lease renewal set has a renewal failure event associated with it that will occur if any lease in the set expires before its membership duration runs out, or if the renewal service attempts to renew a lease and gets a definite exception. Clients can register for this event using methods provided by the set. A registration for this event does not have its own lease, but instead is bundled into the same lease under which the set was granted.

Once placed in a set, a lease will stay there until one or more of the following occurs:

- ◆ The lease on the set itself expires or is cancelled, causing destruction of the set
- ◆ The lease is removed by the client
- ◆ The lease expires
- ◆ The lease's membership expiration arrives
- ◆ A renewal call results in a definite exception

Each lease in a set will be renewed as long as it is in the set. If a renewal call throws an indefinite exception, the renewal service should retry the lease renewal until the lease would otherwise be removed from the set. The renewal service will never cancel a lease. The preferred method of cancelling a lease that has been placed in a set is for the client to first remove the lease from the set and then call `cancel` on it. It is also permissible for the client to cancel the lease without first removing the lease from the set, although this is likely to result in additional network traffic.

The client creates a set by calling the `createLeaseRenewalSet` method. The `leaseDuration` argument specifies how long (in milliseconds) the client wants the set's initial lease duration to be. The initial duration of the set's lease will be equal to or shorter than this request; it will not be longer. This duration must be positive, `Lease.FOREVER`, or `Lease.ANY`; otherwise an `IllegalArgumentException` must be thrown. The set's lease is obtained through a method provided by the set.

The `LeaseRenewalSet` interface defines the interface to the sets created by the lease renewal service. The interface is not a remote interface. Each implementation of the renewal service exports proxy objects that implement the `LeaseRenewalSet` local to the client and use an implementation-specific protocol to communicate with the actual remote server. All of the proxy methods obey normal RMI remote interface semantics except where explicitly noted. The proxy objects for two sets are equal (using the `equals` method) if they are proxies for the same set created by the same renewal service. Any method that communicates with the remote server should throw a `NoSuchObjectException` if the set no longer exists. If a client receives a `NoSuchObjectException` from one of the operations on a lease renewal set the client can infer that the set has been destroyed; however, it should *not* infer that the renewal service has been destroyed.

```
package net.jini.lease;

public interface LeaseRenewalSet {
    public void renewFor(Lease leaseToRenew,
```

```

        long membershipDuration)
    throws RemoteException;

    public EventRegistration setExpirationWarningListener(
        RemoteEventListener listener,
        long minWarning,
        MarshalledObject handback)
    throws RemoteException;

    public void clearExpirationWarningListener()
    throws RemoteException;

    public EventRegistration setRenewalFailureListener(
        RemoteEventListener listener,
        MarshalledObject handback)
    throws RemoteException;

    public void clearRenewalFailureListener()
    throws RemoteException;

    public Lease remove(Lease leaseToRemove)
    throws RemoteException;

    public Lease getRenewalSetLease();
}

```

Leases can be added to the set through the `renewFor` method. The `leaseToRenew` argument specifies the lease to be renewed. An `IllegalArgumentException` must be thrown if the lease was granted by the renewal service itself. An `IllegalArgumentException` must also be thrown if the lease is currently a member of another set allocated by the same renewal service.

---

**Note:** There seem to be two other viable possibilities when a client attempts to add a lease to one set when that lease is already in another set. Adding a lease to a second set can implicitly remove it from the first. This has the nice property of ensuring that for a given lease and lease renewal service, the lease is in at most one set allocated by that lease renewal service. On the other hand I am not wild about the idea of implicitly removing leases from sets when adds are performed. If we decide it is important to support atomically moving a lease from one set to another, I would rather have a `move` method. The second possibility is to allow the same lease in multiple sets and force lease renewal service implementation to

coordinate the renewal of a lease in multiple sets. This makes the implementation of a lease renewal service more complex. It also makes the specification more complex, especially with respect to lease renewal length. For now I am going to go with the `IllegalArgumentException` because I think it will be easier to go from there to the move or multiple set semantics than the other way around.

---

**Note:** We probably need to revisit this decision if we change the lease spec to allow for uncoordinated renewals of the same lease (as opposed to the current idea of generating new leases to the same resource).

---

The `membershipDuration` is the initial membership duration (in milliseconds) for the lease. Unlike a lease duration, the membership duration is unilaterally specified by the client, not negotiated between the client and the service. The duration must have a value between 1 and `Long.MAX_VALUE`, inclusive, or `Lease.ANY`; otherwise the renewal service must throw an `IllegalArgumentException`.

A `membershipDuration` of `Long.MAX_VALUE` does not imply that the lease will remain in the set forever. The lease will be ejected from the set if the set is destroyed, the lease itself expires, the lease is removed from the set, or any renewal attempt made by the renewal service results in a definite exception.

Calling `renewFor` with a lease that is already in the set will associate the existing lease in the set with the new membership duration. The lease is not replaced because it is more likely that the renewal service, rather than the client, has an up-to-date lease expiration. The service is more likely to have an up-to-date expiration because the client should not be renewing a lease that it has passed to a lease renewal service unless the lease is removed first. These semantics also allow `renewFor` to be used in an idempotent fashion.

---

**Note:** These semantics for `renewFor` (and for `remove`, `next`) require that all leases have a reasonable definition for `equals`. This still needs to be formalized in the lease spec.

---

Leases are removed from the set using the `remove` method. Removal from the set will not cause the lease to be cancelled. The method will return the lease that is being removed. The expiration time of the returned lease will reflect either:

- ◆ The result of the last successful renewal call that the renewal service made
- or
- ◆ The expiration time the lease originally had when it was added, if the renewal service has not yet successfully renewed the lease

If the lease is not in the set, `null` will be returned.

The `getRenewalSetLease` method returns the lease associated with the set itself. This method does not make a remote call.

The lease renewal service does not support multiple simultaneous registrations for the same kind of event. Although it would be useful in some limited circumstances, to do so would require event registrations to be leased separately from the set they are associated with. For the average client of the lease renewal service, this ability would increase the number of leases that it would have to manage. Since the renewal service is based on the premise that some clients have difficulty managing their own leases, increasing the number of leases that a client would need to manage could significantly complicate the implementation of those clients. Because there can be at most one listener for each kind of event, a given set provides a `set/clear` interface instead of the more common `addListener/removeListener` interface.

The `setExpirationWarningListener` method allows the client to register for notification of the approaching expiration of the set's lease. The `listener` argument specifies what listener should be notified when the lease is about to expire. The `minWarning` argument specifies in milliseconds how long before lease expiration the event should be generated. This value must be zero or a positive number; if it is not, an `IllegalArgumentException` must be thrown. If the current expiration of the set's lease is sooner than `minWarning`, the event will occur immediately (though it will take time to propagate to the handler).

The `handback` argument to `setExpirationWarningListener` specifies an object that will be part of the expiration warning event notification. This mechanism is detailed in the *Jini™ Distributed Event Specification*.

The `setExpirationWarningListener` method returns the event registration for this event. This registration has the same lease as the lease renewal set. The event ID returned by the event registration is unique, at least with respect to all other active event registrations created by the given renewal service. The method must throw a `NullPointerException` if `listener` is `null`.

If an event handler has already been specified for this event the current registration is replaced with the new one. The returned event registration must have the same event ID as the replaced registration. Because both registrations are for the same kind of event, the events sent to the new registration must be in the same sequence as the events sent to the old registration.

The `clearExpirationWarningListener` method removes the event registration currently associated with the approaching expiration of the set's lease. It is acceptable to call this method even if there is no active registration.

The `setRenewalFailureListener` method allows the client to register for the event associated with the failure to renew a lease in the set. These events are generated when a lease expires while it is still in the set, or the service attempted

to renew the lease and gets a definite exception. The `listener` argument specifies the listener to be notified if a lease could not be renewed.

The `handback` argument to `setRenewalFailureListener` specifies an object that will be part of the renewal failure event notification. This mechanism is detailed in the *Jini™ Distributed Event Specification*.

The `setRenewalFailureListener` method returns the event registration for this event. This registration has the same lease as the set. The event ID returned by the event registration is unique at least with respect to all other active event registrations created by the given renewal service. The method must throw `NullPointerException` if `listener` is `null`.

If an event handler has already been specified for this event the current registration is replaced with the new one. The returned event registration must have the same event ID as the replaced registration. Because both registrations are for the same kind of event, the events sent to the new registration must be in the same sequence as the events sent to the old registration.

The `clearRenewalFailureListener` method removes the event registration currently associated with the event for the failure to renew a lease in the set. It is acceptable to call this method even if there is no active registration.

`ExpirationWarningEvent` objects are passed to the event handlers specified in calls to the `LeaseRenewalSet` method, `setExpirationWarningListener`. The `ExpirationWarningEvent` is a subclass of `RemoteEvent`, adding one additional item of abstract state—the lease which is about to expire. This state is returned by the `getLease` method. Its expiration will reflect the expiration the lease had when the event occurred. Renewal calls may have changed the actual expiration between the time the event was generated and delivered. The event's other state is described in the *Jini™ Distributed Event Specification*. Sequence numbers for a given event ID are increasing. If there is no gap between two sequence numbers, no events have been missed; if there is a gap, events might (but might not) have been missed.

```
package net.jini.lease;

public class ExpirationWarningEvent extends RemoteEvent {
    public ExpirationWarningEvent(Object source,
                                   long eventID,
                                   long seqNum,
                                   MarshallableObject handback,
                                   Lease lease);

    public Lease getLease();
}
```

RenewalFailureEvent objects are passed to the event handlers specified in calls to the LeaseRenewalSet method, setRenewalFailureListener. The RenewalFailureEvent is a subclass of RemoteEvent, adding two additional items of abstract state—the lease which could not be renewed before expiration and the Throwable object that was thrown by the first failed renewal attempt in the last series of consecutive failures. The lease is returned by the getLease method, and the Throwable object by the getThrowable method. If the Throwable object is null it can be assumed that the renewal service was unable to call renew before the lease expired.

```
package net.jini.lease;

public class RenewalFailureEvent extends RemoteEvent {
    public RenewFailureEvent(Object source,
                             long eventID,
                             long seqNum,
                             MarshallableObject handback,
                             MarshallableObject marshalledLease,
                             Throwable throwable);

    public Lease getLease()
        throws IOException, ClassNotFoundException {};

    public Throwable getThrowable();
}
```

The getLease method is declared to throw IOException and ClassNotFoundException, this declaration allows implementations to delay unmarshalling the lease until it is actually needed. Once the getLease method of a given RenewalFailureEvent object returns normally, future calls must return the same object and not may not throw an exception.

If the renewal service was able to renew the lease before the event occurred, the lease's expiration will reflect the result of the last successful renewal call. When a renewal failure event is generated for a given lease, that lease is removed from the set.

The event's other state is as described in the *Jini™ Distributed Event Specification*. Sequence numbers for a given event ID are increasing. If there is no gap between two sequence numbers, no events have been missed; if there is a gap, events might (but might not) have been missed.

---

# The EventMailbox

## 10.1 Overview

The *Jini™ Distributed Event Specification* describes a notification mailbox object for storing event notifications on behalf of other objects. Notification mailboxes can be particularly important for objects that want more control over event notifications. In a distributed system, it may not be desirable for an object to be contacted solely for the purpose of having an event delivered. Objects owned by a mobile node which may detach from a system of Jini technology-enabled services and/or devices is a good example. In this scenario, for the purpose of event notifications, it may be both undesirable as well as not possible to contact such objects. In addition, an object preferring to batch process event notifications may designate a third party to accept events on its behalf. The third party collects events over time until an object initiates their delivery. This chapter defines interfaces and protocols which allow Jini services and clients to interact with a type of third-party event store.

The Jini technology programming model is designed to allow the building of a distributed system that is flexible and robust. The event mailbox service provides a mechanism for alternate delivery semantics for systems built using asynchronous event notifications. While distributed events facilitate the construction of reactive programs, the event mailbox adds the ability for a service to determine how and when events are received. In the distributed event model for Jini technology, the `RemoteEventListener` has no control over how or when an event notification is accepted. Events are delivered by the object that generates the event, referred to as either the *event generator* or simply, the *generator*. Such events may be delivered directly from the event generator to the listener, or indirectly through an arbitrary chain of third-party objects. This delivery is initiated by the generator itself. Through the use of an event mailbox service, the `RemoteEventListener` may accept event notifications at its convenience.

The EventMailbox (in the package `net.jini.event`) will store notifications for other objects until the delivery is requested. Services “advertise” their capabilities by publishing a service interface to a well-known location. Clients that need the service consult the well-known location, download code for the service interface, and initiate requests against it. An interface to an event mailbox service can be acquired from any well-known location capable of storing objects written in the Java programming language. Entities wishing to control how and when event notifications are received may then use this interface to specify the mailbox as a third party for event acceptance and delivery.

## 10.2 Requirements

The requirements of this set of interfaces are:

- ◆ To specify an interface for objects to request use of the mailbox
- ◆ To specify the information that must be returned as a result of such registration
- ◆ To specify client interactions with the mailbox
- ◆ To specify how clients retrieve events from the mailbox

## 10.3 Other Types

The types defined in the specification of the event mailbox service are in the `net.jini.event` package. This specification assumes knowledge of the *Jini™ Distributed Event Specification*. The following object types may be referenced in this chapter. Whenever referenced, these object types will be referenced in unqualified form:

```
java.rmi.RemoteException  
java.io.IOException  
net.jini.core.event.EventRegistration  
net.jini.core.event.RemoteEvent  
net.jini.core.event.RemoteEventListener
```

## 10.4 Model and Terms

Objects contain data and methods that operate on the data. As methods are invoked, the object changes state. One of the defining characteristics of object-oriented programming is that the state of an object is not directly visible by entities other than the object itself. However, there are times that one object may be interested in the occurrence of a particular event within another object. These events are changes in the abstract state of the object, which may or may not be directly reflected in the actual state of the object.

An object may export a set of events which other objects may find of interest. These exported events express abstract state changes about which external objects can ask to be informed. External objects may register interest in such events. Registration for event notification includes specifying the object that will be informed when an instance of an event of interest occurs. This entity may be the object that performed the registration (referred to as the *registrant*) or some other object chosen by the registrant. All that is required of the entity is that it support the `RemoteEventListener` interface. When an event of interest occurs, the object that experienced the abstract state change sends a notification to all listener objects designated to receive such notifications.

A *reactive object*, which takes action based on the occurrence of abstract state changes in other objects on the network, may want more control over how and when events are received. To achieve such controlled delivery, the object could employ the use of a third party to store events on its behalf. At its own convenience, the object may then instruct the third party to forward the collected events. Objects may express their intent to use the third party by registering with it. Registration results in a registration object through which the client of the event mailbox service may instruct the mailbox to forward events to a specified recipient referred to as the *forwarding target* object. The client of the event mailbox service can then dictate when and how events are received by informing the third party when and how to deliver events to the forwarding target.

The event mailbox serves this purpose. The event mailbox service (or simply the *mailbox*) is a third-party object which accepts events on behalf of other objects on the network. When client objects register with the event mailbox, they are, in effect, asking it to provide an object supporting the `RemoteEventListener` interface which can be specified with generator objects to receive events. For any generator, notifying a listener that was obtained from a mailbox results in the event being sent to the mailbox. Over time, the mailbox collects events on behalf of its clients. These events will be presented to forwarding target objects at a later time.

The term *mailbox resources* is used to refer to the `RemoteEventListener` and associated space for collected events allocated by the event mailbox for use by client objects. Mailbox resources are leased resources and, as such, will be main-

tained as long as the associated lease is valid. Since no two environments may be served by a single design trade-off, operational parameters—controls for how the event mailbox deals with issues such as compaction, defragmentation, and low space behavior—may be exposed through an administration interface which can vary across different event mailbox implementations.

## 10.5 The EventMailbox Interface

The EventMailbox is an interface implemented by an object that wants to receive and forward RemoteEvent notifications on behalf of another object. The EventMailbox interface contains a single register method.

```
package net.jini.event;

public interface EventMailbox
{
    MailboxRegistration register(long leaseDuration)
        throws RemoteException;
}
```

The register method has a single parameter of type long, that represents the lease duration for which use of the event mailbox is requested. The register method returns an object of type MailboxRegistration. The value passed in as the requested lease duration must be a positive long value. This value represents the duration, in milliseconds, for use of the event mailbox. The special values defined in the *Jini™ Distributed Leasing Specification*, namely Lease.FOREVER and Lease.ANY, are also valid values. Lease.FOREVER represents a duration of maximum value while Lease.ANY represents a duration whose length is preferred and chosen by the event mailbox. The granted duration for use of the event mailbox service resources is represented as part of a Lease object included in the returned MailboxRegistration object. In granting a lease to the caller of the register method, the event mailbox may grant either the requested duration or a shorter duration. If the register method throws a RemoteException, then registration is not guaranteed to have happened. Each successful invocation of the register method produces a new registration object. Thus, the register method is not idempotent.

## 10.6 The MailboxRegistration Interface

The MailboxRegistration interface abstracts the set of client interactions with the event mailbox service. An object implementing the MailboxRegistration interface is returned to the client as the result of calling the register method of the EventMailbox interface. The details of how a MailboxRegistration object interacts with the underlying event mailbox service is hidden from a holder of the event mailbox registration. Thus, the MailboxRegistration acts like a proxy object.

The encapsulation of what is needed by a client to interact with the event mailbox includes a Lease object, a RemoteEventListener object and methods to disable and enable event delivery. The Lease object represents the usage duration for the resources associated with a RemoteEventListener handed out by the event mailbox. The listener object represents an object capable of being informed of events of interest as specified by the *Jini™ Distributed Event Specification*. To use the event mailbox to accept events on its behalf, an object must specify the listener obtained from the MailboxRegistration object when registering interest in events exported by generator objects. The enableDelivery method is used by objects in possession of the registration object to instruct the event mailbox to deliver events to the specified target listener. The disableDelivery method is used to instruct the event mailbox to stop delivering events.

The getLease method takes no parameters and returns an object of type Lease. The lease on the event mailbox resources is retrieved from the MailboxRegistration by calling getLease, which is a local method call. Should the lease expire or be cancelled, the event mailbox resources associated with the lease are purged.

The getListener method takes no parameters and returns an object of type RemoteEventListener. The returned object, referred to as a *mailbox listener*, is retrieved from the MailboxRegistration by calling the getListener method, which is a local method call. A holder of a mailbox listener object is free to register it with generator objects when expressing interest in a distributed event.

Events are sent by the generator objects through the mailbox listener and collected by the mailbox. The enableDelivery and disableDelivery methods of the MailboxRegistration are used for forwarding collected events. The enableDelivery method takes a single parameter of type RemoteEventListener. The disableDelivery method takes no parameters.

```
package net.jini.event;

public interface MailboxRegistration
{
```

```
public Lease getLease();  
public RemoteEventListener getListener();  
public void enableDelivery(RemoteEventListener target)  
    throws RemoteException;  
public void disableDelivery() throws RemoteException;  
}
```

A forwarding target object may have events delivered as a continuous sequence of events that may be started or halted. This is analogous to turning a faucet on and off. Initially, the faucet is off. When the `enableDelivery` method is called, notification of the specified target listener object with the sequence of events collected by the event mailbox is commenced. Making an `enableDelivery` method call while event delivery has already been enabled updates the target listener as specified in the forwarding target object parameter. An `enableDelivery` call that throws a `RemoteException` is not guaranteed to have successfully enabled delivery of the events stored in the mailbox. Any new events, arriving at the mailbox while the faucet is on, will be accumulated by the mailbox and eventually delivered to the current forwarding target object. An event that is successfully delivered to the forwarding target object is removed from event mailbox storage. The forwarding target object is a `RemoteEventListener`. The event mailbox service delivers events to the forwarding target object by calling its `notify` method. If this call throws a `RemoteException`, the event is not guaranteed to have been sent. An event mailbox implementation may choose to retry such failed delivery attempts. If this call throws a `NoSuchObjectException`, event delivery is halted. The process of sending events continues until the event mailbox has either exhausted its supply of collected events from storage or is instructed to halt delivery. Calling `enableDelivery` with a null forwarding target object halts event delivery.

Calling the `disableDelivery` method instructs the mailbox to halt the delivery of events. Once the `disableDelivery` method has been successfully called, the event mailbox will cease sending events. If `disableDelivery` throws a `RemoteException`, the halting of event delivery is not guaranteed to have succeeded. Making a `disableDelivery` method call after delivery has already been disabled has no effect.

## 10.7 Typical Mailbox Interactions

The following scenarios are examples of typical client interactions with the event mailbox service.

## Scenario 1

A client object performs the following actions when choosing an event mailbox service:

- ◆ Acquires a reference to an EventMailbox
- ◆ Registers with the event mailbox and receives a registration object
- ◆ Stores the event mailbox registration object in stable storage
- ◆ Retrieves the listener from the registration object
- ◆ Registers with event generators specifying the listener obtained from the event mailbox as the place to send events
- ◆ Becomes unable to receive events directly

Suppose a client object intends to register its listener interface with a number of event generators across the network, but wants more control over how and when events are delivered. Because it already knows how to contact these generators, the client is able to register the listener obtained from the event mailbox with the same set of event generators. The registration of the listener with each generator results in events being sent to the mailbox, at which point, all events of interest to the client will be sent through the event mailbox listener registered by the client. The client can control when events are delivered by instructing the event mailbox service to commence delivery at a desirable time. Likewise, the client can have more control over how events are delivered by turning on the event faucet, receiving events, and turning off the faucet after the number of events received reaches a desirable threshold.

## Scenario 2

A client object performs the following actions when initiating delivery of its event notifications:

- ◆ Becomes able to receive events directly
- ◆ Rebuilds mailbox registration object from stable storage if necessary
- ◆ Instructs the event mailbox service to deliver events specifying a valid forwarding target object
- ◆ Instructs the event mailbox service to stop delivering events

A client object that becomes available to receive events prepares to receive them as soon as possible. During the period of time the client was unable to

receive them directly, events meant for the client were delivered to and stored by the event mailbox. The client then retrieves from the event mailbox service all of the events it would have missed had it not employed this service. Use of the event mailbox service is ended when the lease granted by the event mailbox is cancelled or expires. The determination of a reasonable time to terminate this relationship is left to the client object.
